Perioperative complications occur more often in patients with OSA than in healthy controls,[241,242] but the reasons for this observation are unclear. It is challenging to isolate the effect of OSA from the known adverse effects on perioperative outcome of typical OSA comorbidities, such as hypertension, diabetes, coronary artery disease, neurovascular vulnerability, and obesity. Fortunately, severe postoperative complications are uncommon. As a consequence, large trials are needed to isolate the causal relationship between SDB and perioperative complications, such as severe respiratory failure, thromboembolic complications, increased hospital length of stay, and mortality.

Independent of obesity, OSA is not associated with difficult tracheal intubation or mask ventilation.[243-245] However, recent metaanalyses reported a significantly higher risk of postoperative major cardiac and cerebrovascular events, newly detected postoperative atrial fibrillation and acute postoperative respiratory failure, compared with control subjects.[246-248] These findings need to be confirmed in future prospective studies with a larger sample size and a more homogenous population such that confounding factors can be controlled. OSA is associated with postoperative delirium,[241,249] which is an important perioperative complication associated with increased costs, morbidity, and mortality. However, it is currently unclear if this is due to repetitive hypoxia or sleep fragmentation. In contrast, a

recent study using the Nationwide Inpatient Sample database analyzed data from 1,058,710 patients undergoing elective surgery. These authors showed that patients previously diagnosed with SDB had significantly higher rates of emergent mechanical ventilation, use of NIV, and CPAP, as well as increased rates of respiratory failure. Nevertheless, the study also showed that patients with SDB had better outcomes after emergent intubation and had lower care-associated costs compared with their non-SDB counterparts.[250] Similar findings were reported by the same group for data from 91,028 patients undergoing bariatric surgery.[251] In this study, patients with a previous diagnosis of SDB had a shorter hospital length of stay and lower total costs compared with non-SDB patients. The reasons for the differences are unclear. Patients with a known history of sleep apnea may receive more sophisticated perioperative monitoring and more aggressive treatment of their respiratory disease, which might also explain the higher rate of postoperative reintubation in SDB patients reported in the same group.[250] Another possible explanation relates to the consequences of chronic nocturnal desaturation, which can have preventive effects in terms of the consequences of perioperative acute hypoxia. Most importantly, these findings indicate that the association of SDB, and perioperative outcome is likely to be more than a unidirectional relationship. More likely is that SDB could have a dual effect, leading to increased rates of perioperative respiratory complications in patients with SDB, but additionally protecting the same population from the fatal consequences of these complications. The mechanism of the potential link between OSA and postoperative respiratory failure, as well as postoperative delirium, is probably multifactorial. Frequent episodes of airway collapse in OSA lead to hypoxia, disrupted sleep, daytime sleepiness, and increased arousal threshold from sleep, all of which can be considered as potential precipitating or augmenting factors of postoperative complications. It is intriguing to note that patients with OSA appear to be most vulnerable to hypoxia on postoperative night two or three, the time interval during which postoperative delirium most typically manifests.

One population that might deserve additional attention in perioperative care is patients with OHS who, compared with obese patients, are more likely to be admitted to a hospital and require more healthcare resources.[250,252] In addition, higher rates of ICU admission, lengthier long-term care requirements at discharge, and higher mechanical ventilation rates have been reported in patients with OHS compared with severe obese patients without OHS.[251-254]

In summary, patients with SDB are more vulnerable to developing severe perioperative complications. Nevertheless, it is currently unclear whether these complications translate to a poorer overall postoperative outcome for these patients.

PERIOPERATIVE MANAGEMENT IN PATIENTS WITH SLEEP-DISORDERED BREATHING

The standard of care for perioperative management of patients with SDB depends on the severity of the disease, comorbidities, and the threat associated with the planned surgical procedure. It is probably neither feasible nor necessary to conduct a sleep study in all obese patients at risk for sleep apnea who are scheduled for surgery; however, high-risk patients need to be identified and treated perioperatively. Fig. 10.13 shows an algorithm that is being developed by an interdisciplinary international group of clinicians. The algorithm is driven by the idea that patients who have been prescribed CPAP preoperatively should continue to use CPAP perioperatively. Patients who carry several risk factors (procedural and comorbidity-based) may need a preoperative sleep medicine consultation and/or a CPAP prescription.

Preoperative Screening

Several strategies need to be considered to identify patients with SDB adequately.[94,253,254] Although clinical examination is the easiest and most cost-effective method of assessment using predisposing physical characteristics, it has a poor sensitivity and specificity of only 50% to 60% to diagnose OSA accurately.[255,256] However, the clinical value of using questionnaires relates to the fact that they help to identify a high-risk perioperative population, independently of the question of whether an individual patient has OSA. For example, the STOP-Bang questionnaire basically screens for comorbidities of OSA that we know increase the risk of perioperative complications (hypertension, obesity, male sex, older age) rather than direct breathing disorder–associated characteristics. The Score for Prediction of Obstructive Sleep Apnea might also be a helpful tool to predict patients with OSA and its perioperative outcome based on comorbidities and easily available clinical data.[257]

PSG is required to identify SDB specifically, but it cannot be used for preoperative screening of surgical patients. PSG is expensive, may delay surgery, and is inconvenient for the patient. A multistep approach of preoperative screening is required. Preoperative assessment should include a screening for SDB and for the current use of NIV. OSA might not represent real risk in patients scheduled for low-risk procedures from a surgery and anesthesia point of view. The authors believe that patients with no previously diagnosed SDB undergoing a low-risk surgical procedure should receive standard perioperative monitoring and treatment.

Patients undergoing high-risk surgical procedures should receive further workup using a clinical examination combined with standardized and validated questionnaires (e.g., Berlin).[254,258] Although this diagnostic algorithm might be a sufficient screening for OSA, it might be insufficient to detect OHS.[251,253] A blood gas analysis should be considered as a method to detect hypercapnia as a major symptom of OHS (criterion: awake daytime hypercapnia $PaCO_2 \geq 45$ mm Hg). Alternatively, a venous bicarbonate concentration ≥ 27 mmol/L is highly sensitive (92%) for an increased $PaCO_2$, which combined with hypoxemia ($SpO_2 \leq 94\%$) indicates a high risk of OHS in these patients.[251,253,256,259] Of note, OHS is a diagnosis by exclusion. Severe obstructive airway diseases, severe interstitial lung disease, severe chest wall disorders (e.g., kyphoscoliosis), severe hypothyroidism, neuromuscular disease, and congenital central hypoventilation syndrome need to be excluded, and further evaluation of sleep by a sleep medicine specialist before anesthesia should be considered. In these cases, the sleep specialist should determine the optimal diagnostic instruments in cooperation with the perioperative team, prescribe the perioperative auto-titrating CPAP device, and offer in collaboration with respiratory therapy specialists to improve tolerability of perioperative CPAP therapy.

Perioperative Management of Patients with Possible Sleep-Disordered Breathing

Although the data on optimal intraoperative and perioperative management are still limited, and mainly based on studies with low sample size, the techniques and procedures summarized in Box 10.2 might be considered during the perioperative management of patients with SDB.[258] Patients with a history of SDB who are undergoing surgery and anesthesia with high risk of morbidity should receive an "OSA anesthesia bundle" (see Box 10.2) that includes special procedures and preparations during tracheal intubation, extubation, pain therapy, and perioperative CPAP therapy.

Tracheal Intubation. Patients with OSA are frequently obese, and obesity is a risk factor for difficult intubation.[244,259-261] Patients should be preoxygenated efficiently before injection of the anesthetic drug. Sniffing and reverse Trendelenburg position are preferred before intubation, which improves maintenance of the passive (i.e., paralyzed) pharyngeal airway in patients with OSA[260,262] and increases functional residual capacity. To reduce the duration of paralysis, nondepolarizing neuromuscular blocking drugs should be used with caution supported by quantitative neuromuscular transmission monitoring. Immediately after successful intubation, a lung recruitment maneuver and the application of positive end-expiratory pressure for maintaining lung volume during surgery should be considered.[261,263]

Intraoperative Treatment. Impaired upper airway patency is of special concern whenever anesthetics are administered without a device that bypasses the collapsible upper airway—for example, during sedation for endoscopy.[264,265] While the overall rate of overt sedation-related complications for such procedures (e.g., endoscopy) appears low,[266] patients who are vulnerable to respiratory complications may suffer from sequelae of increased upper airway collapsibility beyond the immediately observable after intervention.

Opioids and GABAergic sedatives/hypnotics impair upper airway patency without any meaningful difference between compounds given at an equipotent dose of analgesics.[267-270] Of note, the impairing effects of GABAergic drugs on airway patency can be reversed by the respiratory stimulants (Fig. 10.14).[266] Thus it is recommended not to extubate patients at risk of postoperative airway collapse during hypocarbia but rather at mildly hypercarbic conditions.

Ketamine abolishes the impairment of upper airway patency during loss of consciousness and sleep,[271] and may be a viable adjunct to achieve postoperative pain therapy in patients at high risk of airway collapse.

Nondepolarizing neuromuscular blocking drugs should be titrated optimally by quantitative neuromuscular transmission monitoring to avoid residual neuromuscular blockade, which increases the risk of postoperative respiratory complications.[272-275] The effects of neuromuscular blockade should be reversed only when present, because inappropriate reversal can impair upper airway function in animals and humans.[274-276]

BOX 10.2 Special Sleep-Disordered Breathing Anesthesia Bundle: Special Procedures Performed During Anesthesia in Patients With Diagnosed Sleep-Disordered Breathing and Positive Airway Pressure or Noninvasive Ventilation Treatment

Preanesthesia Period

- Consider regional anesthetic techniques that minimize the chance of postoperative sedation.

Induction Strategy

- Monitoring: capnogram, tidal volume measurement
- Sniffing position
- Reverse Trendelenburg position
- Consider intubation without nondepolarizing NMBA; consider succinylcholine.
- Triple airway maneuver with two hands
- Utilize lung recruitment maneuvers immediately after intubation and apply PEEP for maintaining lung volume during surgery.
- PCV with PEEP
- Short-acting anesthetics and narcotics preferred
- Avoid high-dose steroidal NMBA.
- Use neuromuscular transmission monitoring.

Intraoperative Management

- Whenever possible, use of sedatives and narcotics should be reduced.
- Agents with reduced impairing effect on upper airway patency might be considered (e.g., ketamine, pentobarbital).
- Neuromuscular blockade should be monitored.
- Residual neuromuscular blockade should be reversed.

Extubation and Postanesthetic Care Unit

- Patient should be able to cooperate before extubation. Consider positioning of patients in PACU bed: upper body should be elevated by 45 degrees; lateral position preferred to minimize gravitational effects on the upper airway.
- In case of impaired respiratory function, a plan needs to be defined and documented for monitoring and treatment, including the consideration of noninvasive ventilation.
- Patients will be discharged to an unmonitored environment or home when they meet discharge criteria:
  - Vital signs within 20% from baseline
  - Adequate treatment of nausea
  - Pain score ≤40%
  - Aldrete-score ≥8
  - Passed room air challenge test

Pain Therapy

- Consider nonsteroidal antiinflammatory drugs to reduce opioid use whenever possible, if not contraindicated.
- Use caution when combining opioids with sedatives or hypnotics.

NMBA, Neuromuscular blocking agents; *PACU,* postanesthesia care unit; *PCV,* patient-controlled ventilation; *PEEP,* positive end-expiratory pressure.

Postoperative Care. OSA occurs during sleep and sedation;[277,278] therefore, tracheal extubation should be delayed until complete recovery of consciousness. Patients should be positioned with the upper body elevated by 45 degrees, which improves airway patency[261,262] and functional residual capacity. The lateral body position is an alternative for patients who do not tolerate an elevated upper body position. NIV is a viable treatment of postoperative respiratory failure and helps prevent deoxygenation and the development of postoperative negative pressure pulmonary edema; it can also prevent the respiratory depressant effects of opioids.[276,279]

Before discharge from the post anesthesia care unit, a room air-challenge test should be conducted. Several noninvasive monitoring devices have been developed for patients with and without risk for OSA. However, it is currently unclear if these devices can help prevent postoperative complications, and this requires further investigation.[280,281]

Pain Therapy. Pain treatment is of special concern during the postoperative period. Opioids dose-dependently reduce respiratory drive, and special caution is recommended when opioids are combined with sedatives or hypnotics. If not contraindicated, regional anesthesia and nonopioid analgesics should be considered to reduce opioid use whenever possible. If opioids are used, CPAP treatment throughout the early postoperative period may be beneficial in patients with high risk for OSA.[282] Pain intensity typically decreases over time following surgery. Decreasing opioid doses are typically required to maintain the balance of decreasing and increasing effects on respiratory drive.

Patients with SDB being treated with CPAP at home should proceed with these treatments throughout the perioperative period. Sufficient functioning of the treatment device needs to be checked preoperatively (see Box 10.2).

KNOWLEDGE GAPS AND FUTURE RESEARCH

Although a bold body of evidence on the effect of sleep-disordered breathing throughout the perioperative period has been published during the last decades, there are still large gaps of knowledge.[283,284] Respiratory, cardiovascular, and neuropsychological complications, as well as unfavorable clinical outcomes, may be more or less common in patients with OSA. However, there are many comorbidities that are potential confounders, such as obesity, diabetes, dyslipidemia, coronary artery disease, and increasing age. OSA is a heterogeneous disease, and detailed physiologic phenotyping could identify pathophysiologic mechanisms that increase or decrease risk of perioperative complications of OSA. Multiple mechanistic pathways that can lead to OSA (e.g., compromised anatomy, dilator muscle dysfunction, low arousal threshold, elevated loop gain, inadequate lung volume tethering, and vascular leak) are potentially relevant in a perioperative setting.[125] In-depth physiological studies are required until phenotyping can be accomplished with less time-intensive studies or through PSG. Noninvasive and readily available physiological studies or clinical prediction models that can characterize patients who have high-risk phenotypes of OSA are an important area of future research.

In this context, adequate screening tools for OSA during the perioperative period need to be identified. As stated

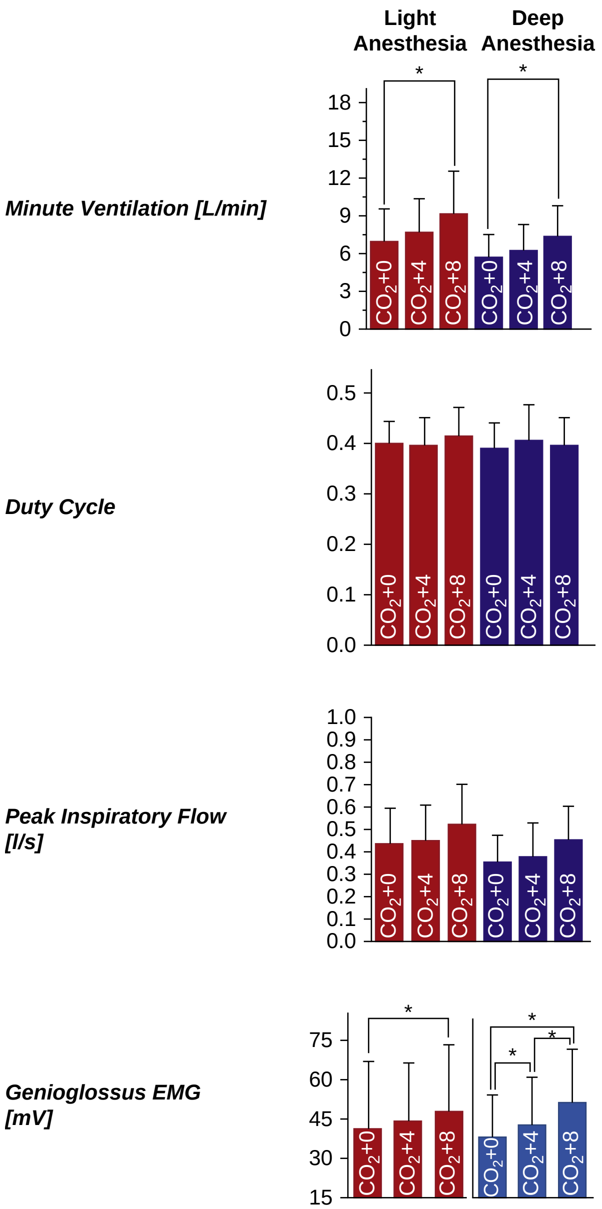

Fig. 10.14 Effect of carbon dioxide (CO2) level on genioglossus activity and respiratory function during anesthesia. Insufflation of CO2 to an increased pCO2 (+4 or +8 mm Hg) increases minute ventilation, peak inspiratory flow and upper airway dilating muscle activity (e.g. genioglossus muscle) in a dose-dependent fashion during deep (blue bars) and light (red bars) anesthesia. (Modified from Ruscic KJ, Bøgh Stokholm J, Patlak J, et al. Supplemental carbon dioxide stabilizes the upper airway in volunteers anesthetized with propofol. *Anesthesiology*. 2018;129(1):37–46.)

previously, PSG is often challenging to schedule before surgery, and ambulatory technologies may be more useful and should be studied. It might even be more important to identify patients at increased risk of postoperative complications due to specific type of surgery, required mode and depth of anesthesia and opioids, as well as other comorbidities, rather than the presence of SDB per se. It is currently unclear to which extent the risk for perioperative complications associated with SDB are due to or modulated by these coexisting factors. In addition, more severe OSA may be developed by some patients with no or mild OSA prior to anesthesia. Challenging factors are opioids, body position, or intravenous fluids.

Some studies found early postoperative monitoring to detect patients with high risk for such aggravation of OSA severity. Additional research is needed to determine if and how postoperative monitoring is able to help stratify the risk for postoperative OSA. During the last few years, different approaches were made to improve postoperative management of patients with OSA (as discussed previously). However, open questions remain: What is the role of supplemental oxygen postoperatively? What are the barriers to CPAP adherence in the perioperative setting? Can patient adherence and positive airway pressure effectiveness be increased with educational resources? Should other respiratory support interventions be examined either in isolation or bundled with positive airway pressure? Is there a role for targeted positive airway pressure therapy, even with CPAP naive patients in very high risk groups? What are the medicolegal liability and patient safety factors to consider when starting CPAP in the hospital?[285]

Future research should aim to answer these questions to further improve the perioperative management of patients with sleep disordered breathing.[283] Testing a bundled approach to care (e.g., an algorithm of care including monitoring, positive airway pressure, education, and other respiratory supports) rather than each component individually might be more useful in initial clinical trials, as this may be more likely to be effective in improving outcomes.

The incidence of perioperative complications is low, and collaborative research networks are needed to identify a sufficient number of patients with OSA and answer the important research questions on perioperative outcomes. Patients with OHS might be at high risk. A minimal set of data elements required in prospective cohort studies should be identified to facilitate multisite collaboration and metaanalysis of independent studies. Case-control studies might also be nested within larger cohort studies. This would facilitate the choice of an appropriate control group. These studies may improve risk stratification and lead to novel targeted therapies. In addition, the identification of interventions that can optimize safety in this population is also important. Initial intervention trials should focus on patients at highest risk for sleep disordered breathing.[283]

Sleep and Sedation in the Intensive Care Unit

Impaired sleep is common in patients in the ICU,[286] with multiple contributing factors including noise, light, interruptions for medical procedures, and administration of fluids and nutrition, as well as endogenous factors such as pain, anxiety, and inflammation. Sleep duration in the ICU is variable depending on environmental conditions and the severity of the patient's disease.[287] Sleep fragmentation occurs consistently during sedation and mechanical ventilation.[288,289] The duration of deep NREM and REM sleep as well as circadian rhythms are severely reduced or abolished in ICU patients.[290-292] About 50% of sleep in these patients occurs during daytime hours.[286,287]. Altered EEG activity, not fitting into the standard criteria for sleep and wakefulness, was reported to occur in up to 70% of ICU patients who were receiving sedatives or being mechanically ventilated.[293] As a result, alternative classifications for sleep in the ICU have been developed;[294] however, these scoring classifications have not yet been validated.

TABLE 10.7 List of Studies Investigating Alteration of Circadian Rhythm and Sleep in Intensive Care Unit Patients

Measurement Method	Interactions	Reference
PSG studies	■ Increased arousal during nighttime and disrupted sleep, due to: ▪ noise ▪ dim light ▪ medical intervention	292,296
	■ Decrease N3- and REM-sleep ■ Increase arousals and awakenings	302-304
	■ Multiple discrete sleep episodes per 24 h ■ Atypical EEG signal: ▪ disrupted sleep ▪ nonphysiologic sleep ▪ architecture, or evidence of coma	287,290,292,294
Melatonin blood levels and urinary 6-sulfatoxymelatonin urine levels	■ Increasing chronodisruption with disease severity (rehabilitation patients, ICU patients, ICU patients with severe sepsis) ■ Delayed melatonin peak at night	292,304-312
	■ Reduced physiologic melatonin secretion at night, due to: ▪ sedation ▪ mechanical ventilation ▪ increased arousal	305,308,309
	■ Increased melatonin levels during the day, due to: ▪ dim light ▪ severe sepsis	306,311
Blood pressure variation	■ Reduced nocturnal blood pressure dip	305
Body temperature variation	■ Reduced temperature variation ■ Altered circadian rhythm with nadir dispersed widely across 24 h	23,305,313
Plasma cortisol level	■ Abolished circadian rhythm ■ Delayed peak of cortisol levels	305,310

EEG, Electroencephalography; *ICU*, intensive care unit; *N3,* sleep stage 3; *PSG,* polysomnography; *REM,* rapid eye movement.

NOISE AND LIGHT EXPOSURE

ICUs are among the most noisy areas in hospitals, with sound levels often exceeding those recommended by the World Health Organization (<45 dB).[289,295] Elbaz and associates[296] reported an increased incidence of arousals at sound levels above >77 dB in stable, mechanically ventilated ICU patients during the weaning phase. In the ICU setting, alarms from medical and monitoring devices were the most significant source of noise.

In addition to noise, changes in light exposure can alter sleep patterns and circadian rhythms. ICU patients are often exposed to dim light throughout the 24-hour cycle, resulting in increased light levels during the night and insufficient light exposure during the daytime.[297,298] This hinders the alignment (photoentrainment) of the internal circadian clock to the external 24-hour rhythm, potentially resulting in the disrupted sleep-wake pattern seen in many ICU patients.[299]

Impaired rhythmicity in melatonin secretion pattern in critically ill patients was reported in several studies (Table 10.7 for overview), and multiple factors influence melatonin rhythm in the ICU. Melatonin levels decrease with increasing age,[300] making older ICU patients more sensitive to circadian rhythm disruptions. Opioids increase melatonin levels throughout the 24-hour period.[301]

Similarly, β-agonists, including vasopressors, positive inotropes, and aerosolized albuterol, increase melatonin levels, whereas β-blockers decrease melatonin secretion. Also, endogenous production of catecholamines may induce periodic melatonin increases in patients with critical illness.[305] Benzodiazepines have inconsistent effects on melatonin.[314,315]

These interactive effects of critical illness and ICU treatment should be acknowledged while caring for ICU patients. Reduction of light and noise exposure during the night, and increased light levels during the day are recommended to improve sleep. In addition, earplugs and eye masks have been shown consistently to improve sleep quality in ICU patients and possibly reduce the risk of complications.[316-319]

MEDICATION AND MEDICAL PROCEDURES

Interruptions of sleep due to medical or nursing procedures are environmental factors in the ICU. Studies in different ICU settings found high numbers of interventions to be performed during the nighttime, ranging up to 60 interventions per night.[320-322]

Both NIV and ventilation via breathing tube impair sleep architecture and quality.[288,323] It is unclear how the issue of ICU-associated circadian disruption can be prevented or treated. Data suggest that weaning procedures during the daytime combined with assist control ventilation during the nighttime improve sleep, expressed as reduced numbers of arousal in patients requiring long-term ventilation.[291]

SLEEP AND SEDATION IN THE INTENSIVE CARE UNIT

Sedation is frequently required in the ICU to treat excessive agitation or to fulfill specific therapeutic needs; however, heavy sedation is associated with prolonged ICU and hospital stays.[324] GABA receptor agonists, such as propofol and benzodiazepines, may reduce REM sleep.[325,326]

Pain is a common experience for most patients in the ICU,[327] and failure to recognize pain can result in excessive administration of sedatives.[324] However, opioids have been shown to decrease REM-sleep and worsen sleep disorders, such as OSA in ICU patients.[131,328] Accordingly, an aggressive approach to managing pain while minimizing opioid utilization has been recommended.[329]

PHARMACOLOGICAL TREATMENT OF SLEEP DISTURBANCES IN INTENSIVE CARE UNIT PATIENTS

Medications currently used for the treatment of insomnia in the ICU interact with the GABA system. GABAergic neurotransmission has multiple functions throughout the brain, leading to daytime sedation, confusion, anterograde amnesia, and delirium.[330-332]

Melatonin has been selected as alternative sleep-promoting medication for critically ill patients in some countries. However, studies on the use of melatonin for the treatment of sleep disturbances and potential complications (e.g., delirium) in ICU patients have produced conflicting results. Administration of melatonin improved subjective and objective sleep quality in a small number of studies.[333-335] Melatonin may have side-effects such as dizziness, nausea, drowsiness, hypotension, and headache, potentially critical in the ICU setting. Recently melatonin receptor agonists have been developed and marketed for patients with circadian rhythm disorders.[336,337] These drugs may have fewer off-target effects than melatonin, but studies on their application in the ICU are very limited. It is therefore difficult to recommend treatment with melatonin agonists of any kind for ICU patients.[338]

The orexin receptor antagonist suvorexant has been approved by the FDA for the treatment of primary insomnia and might be another promising new approach for the treatment of insomnia in ICU patients. In a 4-week study in 254 patients with primary insomnia, suvorexant significantly improved sleep efficiency from the first night until the end of the study compared with placebo in a dose-dependent manner. In addition, suvorexant significantly improved wake after sleep onset and reduced sleep latency,[339] without an apparent delirium-promoting effect.[340] Additional research in the efficacy and safety of orexin receptor antagonists with critically ill patients is needed.

CONSEQUENCES OF SLEEP DISTURBANCE IN ICU PATIENTS

Compelling evidence links good sleep to proper metabolic, endocrine, immune, and neurobehavioral function.[341-345]

Regardless of controversies, the importance of a sufficient amount of good quality sleep for proper immunologic function, as well as the increased susceptibility for infection due to sleep loss, has gained increased acceptance.[346] Sleep deprivation during influenza vaccination delays the increase of antibody titers.[347,348] Sleep deprivation and insomnia is associated with decreased phagocytic activity of lymphocytes and natural killer T-cells, as well as lower levels of interleukin 2[349] and interleukin 7.[350] Interleukin 7 facilitates the transition of CD8þ effector to memory T-cells and lengthens survival of the T-cell memory cells.[351] Prolonged sleep deprivation, as may occur in long term ICU patients, may induce a persistent production of proinflammatory cytokines, producing a chronic low-grade inflammation, as well as immunodeficiency.[348]

Even short sleep deprivation in otherwise healthy young subjects has been shown to be associated with impaired glucose tolerance and insulin resistance, similar to levels usually seen in patients in the early course of diabetes mellitus.[352] In addition, sleep deprivation can induce the onset of a catabolic state: increased oxygen consumption, carbon dioxide production, and catecholamine levels, likely as signs of a stress response.[353] Changes in the activity of the hypothalamo-pituitary-adrenal axis with altered plasma levels of cortisol and thyrotropin,[354] as well as increased levels of inflammatory cytokines, are seen during sleep deprivation.[355]

It is likely that postoperative sleep deprivation also affects respiratory function, characterized as increased vulnerability to respiratory muscle fatigue,[356] decrease in ventilatory response to hypercapnia,[357] and greater upper airway collapsibility.[358]

Cognitive impairment after even short-term sleep deprived conditions is intuitive. Sleep deprivation causes bidirectional changes in brain activity and connectivity, thereby mainly affecting attention and working memory, and an increased vulnerability to delirium in critically ill patients.[359-361]

In addition, recent studies found beneficial effects of realignment of the sleep-wake cycles by pharmacologic and chronotherapeutic methods on the risk for delirium in these patients.[362-364] However, sleep-promoting agents per se can increase the vulnerability to delirium, and the optimal sleep-promoting agent that also minimizes the risk of delirium needs to be identified.

PERIOPERATIVE MANAGEMENT OF OTHER SLEEP DISORDERS

Narcolepsy

Narcolepsy is a neurologic sleep disorder with a prevalence of 0.05% to 0.8% in most ethnic groups.[365,366] It is characterized by excessive daytime sleepiness, involuntary daytime sleep episodes, disturbed nocturnal sleep, and sleep-associated muscular hypotension. Narcolepsy is divided into narcolepsy with or without cataplexy (sudden loss of muscle tone without loss of consciousness).[367]

An autoimmune pathology against hypothalamic orexin neurons may be involved in the pathogenesis of narcolepsy.[366] A mutation of the HCRT receptor 2 or loss of HCRT neurons have been shown to cause a narcolepsy-like state in animals,[368] and the deficiency of HCRT has been shown to be associated with narcolepsy in humans.[34] HCRT is involved in control of several biological functions such as feeding, cardiovascular regulation, upper airway stability, pain, locomotion, stress, and addiction.[369,370] Environmental factors play a key role in the pathogenesis of the disorder, as the disease concordance rate between monozygotic twins is only 20% to 35%.

Treatment of narcolepsy consists of behavioral treatment, as well as pharmacologic treatment for (1) daytime sleepiness and (2) cataplexies. Periodic and regular sleep times and scheduled daytime naps are recommended. Pharmaceutical treatments of daytime sleepiness include amphetamines, methylphenidate, modafinil, or selegiline (also effective for treatment of cataplexy), and cataplexies can be treated using tricyclic antidepressants, selective serotonin reuptake inhibitors, or γ-hydroxybutyrate/sodium oxybate. Medical treatment should always be accompanied by behavioral therapy.

Delayed emergence from anesthesia, postsurgical hypersomnia, and apneic episodes are in part related to an increased sensitivity to anesthetic drugs in narcolepsy patients.[371-373] Monitoring of anesthetic depth might be recommended in this patient population. Medical treatment of narcolepsy should be maintained during the preoperative period.[374,375] The most commonly used treatment of daytime sleepiness is modafinil, which acts via dopaminergic pathways and accelerates emergence from anesthesia.[376,377] Avoidance of sedative premedication and consideration of regional anesthesia may be indicated.[378] Of note, cataplectic events can also occur during regional anesthesia.[379]

Restless Legs Syndrome and Periodic Limb Movement Disorder

Restless legs syndrome, or Ekbom syndrome, is a neurologic disorder with a prevalence of 2% to 5% as defined by four cardinal features, including (1) the urge to move the limbs, usually associated with paresthesias or dysesthesias, (2) aggravating effects of rest, (3) ameliorating effects of physical activity, and (4) symptoms that worsen during the course of day, with a peak during the evening or at night. Patients with restless legs syndrome usually also complain about sensory symptoms in the legs.

Isolated periodic limb movement during sleep is a rare symptom, commonly referred to as *periodic limb movement disorder*. The characteristic periodic episodes of repetitive limb movements during sleep occur most often in the lower extremities, but occasionally in the upper extremities. These movements can be associated with frequent arousals leading to sleep disruption, causing excessive daytime sleepiness, which often is the only symptom reported by the patients themselves in most cases.[380]

Symptomatic restless legs syndrome can occur in patients with iron deficiency and uremia, during pregnancy,[381] or during the use of neurotropic medications (dopamine antagonists, neuroleptics, selective serotonin reuptake inhibitors, tricyclic antidepressants, antihistamines, caffeine, alcohol, nicotine). Although daytime symptoms of restless legs syndrome can be sufficiently diagnosed clinically (clinical examination in combination with standardized questionnaires), a PSG is recommended to rule out SDB, especially in patients complaining of daytime sleepiness or sleep fragmentation.

According to the most recent guidelines of the AASM, the first-line treatment of restless legs syndrome should consist of dopamine agonists (i.e., ropinirole and pramipexole) in the evening. Furthermore, gabapentin enacarbil, levodopa with dopa decarboxylase inhibitor, or opioids can be used. Medication impairing the dopaminergic system (dopamine antagonists, neuroleptics, selective serotonin reuptake inhibitors, and tricyclic antidepressants, antihistamines, caffeine, alcohol, and nicotine) should be avoided, if possible.

Exacerbation of restless legs syndrome may occur after general anesthesia,[382] and the urge to move the limbs may be misinterpreted as agitation or delirium.[383] The first manifestation of restless legs syndrome may occur after spinal anesthesia[384] or general anesthesia,[384] and the prevalence of restless legs syndrome after surgery seems to be higher than expected in this population.[382] To prevent perioperative exacerbation of symptoms, patients with restless legs syndrome should be scheduled for surgery early in the day. Restless legs syndrome medication should be continued until the day of surgery, whenever appropriate. Drugs that block the central dopamine transmission, such as neuroleptics, should be avoided. In contrast, ketamine might be the superior anesthetic drug for patients with restless legs syndrome.[385] In addition, intravenous or subcutaneous opioids and benzodiazepines during and after the surgery procedure might be beneficial in patients with restless legs syndrome. The best way to provide symptom relief in patients with restless legs syndrome might be early mobilization after surgery. In patients who are not eligible for mobilization, compression treatment[386] or intravenous administration of magnesium[387] and physiostigmine[388] have been shown to lead to relief of restless legs syndrome symptoms. Iron and ferritin blood levels should be monitored closely before, during, and after surgery, especially in surgical cases with iron loss (i.e., bleeding), to prevent symptomatic restless legs syndrome symptoms.

Acknowledgment

The editors, publisher, and Drs. Sebastian Zaremba and Matthias Eikermann would like to thank Dr. Nancy L. Chamberlin for her contribution to this chapter in the prior edition of this work. It has served as the foundation for the current chapter.

Cerebral Physiology and the Effects of Anesthetic Drugs

PIYUSH M. PATEL, JOHN C. DRUMMOND, and BRIAN P. LEMKUIL

KEY POINTS

- The brain has a high metabolic rate and receives approximately 12% to 15% of cardiac output. Under normal circumstances, cerebral blood flow (CBF) is approximately 50 mL/100 g/min. Gray matter receives 80% and white matter receives 20% of this blood flow.
- Approximately 60% of the brain's energy consumption supports electrophysiologic function. The remainder of the energy consumed by the brain is involved in cellular homeostatic activities.
- CBF is tightly coupled to local cerebral metabolism, a process called *neurovascular coupling*. When cerebral activity in a particular region of the brain increases, a corresponding increase in blood flow to that region takes place. Conversely, suppression of cerebral metabolism leads to a reduction in blood flow.
- CBF is autoregulated and remains constant over a mean arterial pressure (MAP) range estimated at 65 to 150 mm Hg, given normal venous pressure. CBF becomes pressure passive when MAP is either less than the lower limit or more than the upper limit of autoregulation. The lower and upper limits, as well as the range and slope of the plateau, manifest significant variability between individuals.
- CBF is also under chemical regulation. CBF varies directly with arterial carbon dioxide tension ($PaCO_2$) in the range of 25 to 70 mm Hg. When arterial partial pressure of oxygen (PaO_2) decreases to less than 60 mm Hg, CBF increases dramatically. Reductions in body temperature influence CBF primarily by the suppression of cerebral metabolism.
- Systemic vasodilators (e.g., nitroglycerin, nitroprusside, hydralazine, and calcium channel blockers) vasodilate the cerebral circulation and can, depending on the MAP, increase CBF. Vasopressors such as phenylephrine, norepinephrine, ephedrine, and dopamine do not have appreciable direct effects on the cerebral circulation. Their effect on CBF is via their effect on arterial blood pressure. When the MAP is less than the lower limit of autoregulation, vasopressors increase the MAP and thereby increase CBF. If the MAP is within the limits of autoregulation, then vasopressor-induced increases in systemic pressure have little effect on CBF.
- All volatile anesthetics suppress cerebral metabolic rate (CMR) and, with the exception of halothane, can produce burst suppression of the electroencephalogram. At that level, the CMR is reduced by approximately 60%. Volatile anesthetics have dose-dependent effects on CBF. In doses less than the minimum alveolar concentration (MAC), CBF is modestly decreased. In doses larger than 1 MAC, direct cerebral vasodilation results in an increase in CBF and cerebral blood volume (CBV).
- Barbiturates, etomidate, and propofol decrease the CMR and can produce burst suppression of the electroencephalogram. At that level, the CMR is reduced by approximately 60%. Because neurovascular coupling is preserved, CBF is decreased. Opiates and benzodiazepines effect minor decreases in CBF and CMR. In contrast, ketamine can increase CBF significantly, in association with a modest increase in CMR.
- Brain stores of oxygen and substrates are limited, and the brain is extremely sensitive to decreases in CBF. Severe decreases in CBF (<6-10 mL/100 g/min) lead to rapid neuronal death. Ischemic injury is characterized by early excitotoxicity and delayed apoptosis.
- Barbiturates, propofol, ketamine, volatile anesthetics, and xenon have neuroprotective efficacy and can reduce ischemic cerebral injury in experimental models. This anesthetic neuroprotection is sustained only when the severity of the ischemic insult is mild; with moderate-to-severe injury, long-term neuroprotection is not achieved. The neuroprotective efficacy of anesthetics in humans is limited. Administration of etomidate can decrease regional blood flow, which can exacerbate ischemic brain injury.

This chapter reviews the effects of anesthetic drugs and techniques on cerebral physiology—in particular, their effects on cerebral blood flow (CBF) and metabolism. The final section presents a brief discussion of pathophysiologic states, including cerebral ischemia and cerebral protection. Attention is directed to the rationale for selection and appropriate use of the anesthetic agents for neuroanesthetic management. Chapter 57 presents the clinical management of these patients in detail. Neurologic monitoring, including the effects of anesthetics on the electroencephalogram (EEG) and evoked responses, is reviewed in Chapter 39.

The Anatomy of the Cerebral Circulation

The arterial blood supply to the brain is composed of paired right and left internal carotid arteries, which give rise to the anterior circulation, and paired right and left vertebral arteries, which give rise to the posterior circulation. The connection of the two vertebral arteries forms the basilar artery. The internal carotid arteries and the basilar artery connect to form a vascular loop called the circle of Willis at the base of the brain that permits collateral circulation between both the right and left and the anterior and posterior perfusing arteries. Three paired arteries that originate from the circle of Willis perfuse the brain: anterior, middle, and posterior cerebral arteries. The posterior communicating arteries and the anterior communicating artery complete the loop. The anterior and the posterior circulations contribute equally to the circle of Willis.

Under normal circumstances, blood from the anterior and posterior circulations does not admix because the pressures in the two systems are equal. Similarly, side-to-side admixing of blood across the circle is limited. The vessels that originate from the circle provide blood flow to well-delineated regions of the brain. However, in pathologic circumstances during which occlusion of one of the arterial branches occurs, the circle of Willis can provide anterior-posterior or side-to-side collateralization to deliver flow to the region of the brain with reduced perfusion.

A complete circle of Willis is shown in Fig. 11.1*A*. However, substantial variability exists in the anatomy of the circle of Willis, and a significant proportion of individuals may have an incomplete circular loop.[1] The variations in the circle and their prevalence are shown in Fig. 11.1*B*.

Three sets of veins drain blood from the brain. The superficial cortical veins are within the pia mater on the brain's surface. Deep cortical veins drain the deeper structures of the brain. These veins drain into dural sinuses, of which the superior and inferior sagittal sinuses and the straight, transverse and sigmoid sinuses are the major dural sinuses. These ultimately drain into the right and left internal jugular veins.A schematic representation of the cerebral venous circulation is shown in Fig. 11.1*C*.

There is considerable asymmetry in the blood flow between the right and left internal jugular veins. In approximately 65% of patients, flow in the right IJV is greater than in the left; in the remainder, the left IJV is dominant.[2] The pattern of venous drainage may have implications for insertion of jugular venous catheters for the measurement of jugular venous oxygen saturation ($SjVO_2$). To ensure accurate measurement of $SjVO_2$, it has been advocated that the catheter be inserted into the dominant jugular vein. In most patients, the right IJV will be the dominant vein.

CEREBROSPINAL FLUID FORMATION AND CIRCULATION

Cerebrospinal fluid (CSF) is produced primarily by the choroid plexus in the lateral, third, and fourth ventricles; there are small contributions from the endothelial cells and from fluid that is produced as a consequence of metabolic activity. CSF production is the result of hydrostatic efflux from capillaries into the perivascular space, and then active transport into the ventricles. CSF reabsorption occurs primarily via the arachnoid granulations present in the dural sinuses. A smaller proportion of CSF, which tracks along cranial and peripheral nerves, perivascular routes, and along white matter tracts, gains access to the cerebral venous system by transependymal flow. The total CSF space is approximately 150 mL and total daily CSF production averages 450 mL. Therefore, there is a substantial daily turnover of CSF. CSF production is also under the influence of the circadian rhythm, with the peak production of CSF occurring during sleep.[3]

Recently, the concept of the glymphatic pathway as a means by which waste products are removed from the brain has been advanced. Conceptually, the glymphatic pathway can be visualized as a system akin to the lymphatic system in the systemic circulation (note, however, that the brain does not contain lymphatics other than those present in the meninges). Functionally, CSF enters the periarterial space, a space that is bounded by the vessels and the end-feet of astrocytes. Aquaporin channels on the end-feet facilitate this water exchange. From the periarterial space, CSF is transported to the brain parenchyma, and from there to the perivenous space and on to the ventricles. As such, the glymphatic system serves as a waste disposal system.[3] Of considerable interest is the observation that the periarterial space increases significantly during sleep and during general anesthesia; hence, glymphatic transport and waste clearance is increased during these states. Among anesthetic agents, glymphatic transport is reduced by volatile agents but is less affected by dexmedetomidine.[4]

REGULATION OF CEREBRAL BLOOD FLOW

Anesthetic drugs cause dose-related and reversible alterations in many aspects of cerebral physiology, including CBF, cerebral metabolic rate (CMR), and electrophysiologic function (EEG, evoked responses). The effects of anesthetic drugs and techniques have the potential to adversely affect the diseased brain and are thus of clinical importance in patients with neurosurgical disease. Conversely, the effects of general anesthesia on CBF and CMR can be altered to improve both the surgical course and the clinical outcome of patients with neurologic disorders.

The adult human brain weighs approximately 1350 g and therefore represents approximately 2% of total body weight. However, it receives 12% to 15% of cardiac output. This high flow rate is a reflection of the brain's high metabolic rate. At rest, the brain consumes oxygen at an average

rate of approximately 3.5 mL of oxygen per 100 g of brain tissue per minute. Whole-brain oxygen consumption (50 mL/min) represents approximately 20% of total body oxygen utilization. Normal values for CBF, CMR, and other physiologic variables are provided in Box 11.1.

Approximately 60% of the brain's energy consumption supports electrophysiologic function. The depolarization-repolarization activity that occurs, reflected in the EEG, requires expenditure of energy for the maintenance and restoration of ionic gradients and for the synthesis, transport, release, and reuptake of neurotransmitters. The remainder of the energy consumed by the brain is involved in cellular homeostatic activities (Fig. 11.2). Local CBF and CMR within the brain are very heterogeneous, and both are approximately four times greater in gray matter than in white matter. The cell population of the brain is also heterogeneous in its oxygen requirements. Glial cells make up approximately one half of the

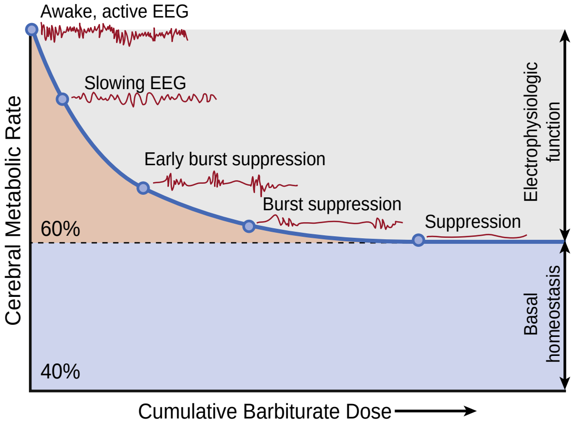

Fig. 11.2 Interdependency of cerebral electrophysiologic function and cerebral metabolic rate (CMR). Administration of various anesthetics, including barbiturates, results in a dose-related reduction in the CMR of oxygen ($CMRO_2$) and cerebral blood flow (CBF). The maximum reduction occurs with the dose that results in electrophysiologic silence. At this point, the energy utilization associated with electrophysiologic activity has been reduced to zero, but the energy utilization for cellular homeostasis persists unchanged. Additional barbiturates cause no further decrease in CBF or $CMRO_2$. *EEG,* Electroencephalogram.

brain's volume and require less energy than neurons. Besides providing a physically supportive latticework for the brain, glial cells are important in the reuptake of neurotransmitters, in the delivery and removal of metabolic substrates and wastes, and in blood-brain barrier (BBB) function.

Given the limited local storage of energy substrate, the brain's substantial demand for substrate must be met by adequate delivery of oxygen and glucose. However, the space constraints imposed by the noncompliant cranium and meninges require that blood flow not be excessive. Not surprisingly, elaborate mechanisms regulate CBF. These mechanisms, which include myogenic, chemical, and autonomic neural factors, are listed in Table 11.1.

MYOGENIC REGULATION (AUTOREGULATION) OF CEREBRAL BLOOD FLOW

The conventional view of autoregulation is that the cerebral circulation adjusts its resistance to maintain CBF relatively constant over a wide range of mean arterial pressure (MAP) values. In normal human subjects, CBF is autoregulated between 70 mm Hg (lower limit of autoregulation, LLA) and 150 mm Hg (upper limit of autoregulation, ULA) (Fig. 11.3).[5] There is, however, considerable variation between subjects in the autoregulation limits. Cerebral perfusion pressure is the difference between the MAP and the intracranial pressure (ICP). Because ICP is not usually measured in normal subjects, cerebral perfusion pressure (CPP = MAP − ICP) is rarely available. Assuming a normal ICP of 5 to 10 mm Hg in a supine subject, an LLA of 70 mm Hg expressed as MAP corresponds to a LLA of approximately 60 to 65 mm Hg expressed as CPP. Above and below the autoregulatory plateau, CBF is pressure-dependent (pressure-passive) and linearly varies with CPP. Autoregulation is influenced by the time course over which the changes in CPP occur. Even within the range over which autoregulation normally occurs, a rapid change in arterial pressure will result in a transient (i.e., 3-4 minute) alteration in CBF.

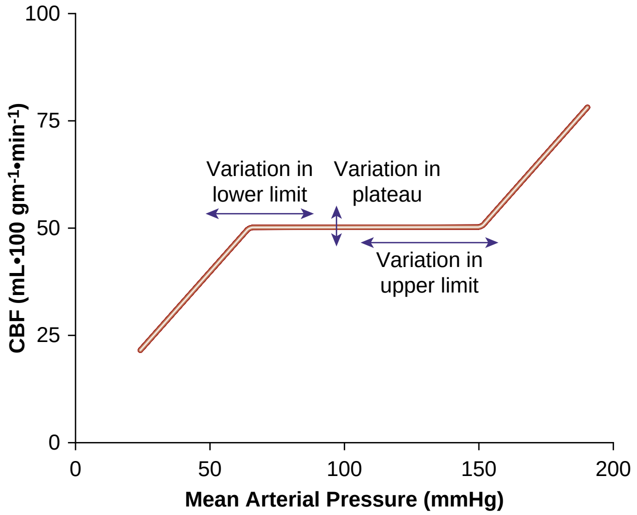

Fig. 11.3 The conventional view of cerebral autoregulation. Cerebral blood flow (CBF) is maintained within the normal range in the face of widely varying blood pressures. Below the lower limit of autoregulation, approximately 65 to 70 mm Hg in humans, and above the upper limit, approximately 150 mm Hg, the cerebral circulation is pressure passive and CBF decreases or increases, respectively, with corresponding changes in mean arterial pressure. Note that there is considerable intersubject variation in the limits of the autoregulatory plateau; the extent of this variation is depicted by the arrows. The autoregulatory curve should not be considered fixed and static but as a dynamically changing response to the cerebral circulation to changes in blood pressure.

The limits of autoregulation and the autoregulatory plateau are conceptual frameworks for the purpose of analysis. They do not represent physiologic "all-or-none" responses. There is considerable variability in the LLA and ULA as well as in the limits of the plateau (see the section on "An Integrated Contemporary View of Cerebral Autoregulation").

The precise mechanisms by which autoregulation is accomplished and its overlap with neurovascular coupling are not known. According to the myogenic hypothesis, changes in CPP lead to direct changes in the tone of vascular smooth muscle; this process appears to be passive. Nitric oxide (NO) and calcium channels may participate in the vasodilation associated with hypotension.

CHEMICAL REGULATION OF CEREBRAL BLOOD FLOW

Several factors, including changes in CMR, arterial partial pressure of carbon dioxide ($Pa\text{CO}_2$), and arterial partial pressure of oxygen ($Pa\text{O}_2$) cause alterations in the cerebral biochemical environment that result in adjustments in CBF.

Cerebral Metabolic Rate

Regional CBF and metabolism are tightly coupled. They involve a complex physiologic process regulated, not by a single mechanism, but by a combination of metabolic, glial, neural, and vascular factors. Increased neuronal activity results in increased local brain metabolism, and this increase in the CMR is associated with a proportional change in CBF referred to as *neurovascular coupling*. The traditional view of neurovascular coupling is that it is a positive feedback mechanism wherein increased neuronal activity results in a demand for energy; this demand is met by an increase in CBF. More recent data indicate that coupling is based on a feed-forward mechanism wherein neuronal activity directly increases CBF, thereby increasing energy supply.[6] Although the precise mechanisms that mediate neurovascular coupling have not been defined, the data available implicate local by-products of metabolism (e.g., potassium ion [K^+], hydrogen ion [H^+], lactate, adenosine, and adenosine triphosphate [ATP]). Increased synaptic activity with the attendant release of glutamate leads to the downstream generation of a variety of mediators that affect vascular tone (Fig. 11.4). Glutamate, released with increased neuronal activity, results in the synthesis and release of NO, a potent cerebral vasodilator that plays an important role in neurovascular coupling. Glia also play an important role in neurovascular coupling. Their processes make contact with neurons, and these processes may serve as conduits for the coupling of increased neuronal activity to increases in blood flow. Glutamate activation of metabotropic glutamate receptors (mGluR) in astrocytes leads to arachidonic acid (AA) metabolism and the subsequent generation of prostaglandins and epoxyeicosatrienoic acids. Oxygen modulates the relative contribution of these pathways, and in the setting of reduced oxygen tension at the tissue level, the release of adenosine can contribute to vascular dilation. The net result therefore on vascular tone is determined by the relative contribution of multiple signaling pathways. In addition, nerves that innervate cerebral vessels release peptide neurotransmitters such as vasoactive intestinal peptide (VIP), substance P, cholecystokinin, somatostatin, and calcitonin gene–related peptide. These neurotransmitters may also potentially be involved in neurovascular coupling.

CMR is influenced by several phenomena in the neurosurgical environment, including the functional state of the nervous system, anesthetic drugs, and temperature.

Functional state. CMR decreases during sleep and increases during sensory stimulation, mental tasks, or arousal of any cause. During epileptic activity, increases in the CMR may be extreme, whereas regionally, after brain injury and globally with coma, the CMR may be substantially reduced.

Anesthetic drugs. The effect of individual anesthetic drugs on the CMR is presented in greater detail in the second section of this chapter. In general, anesthetic drugs suppress the CMR, with the exception of ketamine and nitrous oxide (N_2O). The component of the CMR on which they act is electrophysiologic function. With several anesthetics, including barbiturates, isoflurane, sevoflurane, desflurane, propofol, and etomidate, increasing plasma concentrations cause progressive suppression of EEG activity and a concomitant reduction in the CMR. However, increasing the plasma level beyond what is required to first achieve suppression of the EEG results in no further depression of the CMR. The component of the CMR required for the maintenance of cellular integrity, the "housekeeping" component, is unaltered by anesthetic drugs (see Fig. 11.2).

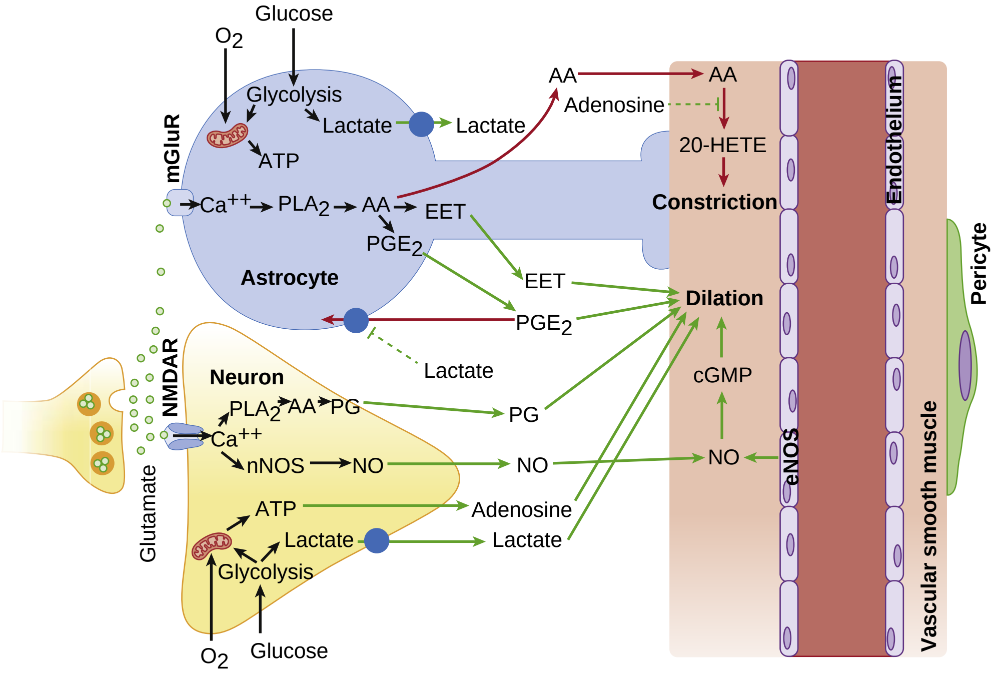

Fig. 11.4 Cerebral neurovascular coupling. Synaptic activity leads to glutamate release, activation of glutamatergic receptors, and calcium entry in neurons. This results in a release of arachidonic acid *(AA)*, prostaglandins *(PGs)*, and nitric oxide *(NO)*. Adenosine and lactate are generated from metabolic activity. These factors all lead to vascular dilation. Glutamate also activates metabotropic glutamate receptors *(mGluR)* in astrocytes, causing intracellular calcium entry, phospholipase A_2 *(PLA_2)* activation, release of AA and epoxyeicosatrienoic *(EET)* acid and prostaglandin E_2 *(PGE_2)*. The latter two AA metabolites contribute to dilation. By contrast, AA can also be metabolized to 20-hydroxyl-eicosatetraenoic acid *(20-HETE)* in vascular smooth muscle. 20-HETE is a potent vascular constrictor. *cGMP,* Cyclic guanosine monophosphate; *eNOS,* endothelial nitric oxide synthase; *NMDAR, N*-methyl D-aspartate (NMDA) glutamate receptor; *nNOS,* neuronal nitric oxide synthase. (Modified from Attwell D, Buchan AM, Charpak S, et al. Glial and neuronal control of brain blood flow. *Nature.* 2010;468(7321):232–243.)

When the complete suppression of EEG is achieved, the cerebral metabolic rate of oxygen ($CMRO_2$) is similar irrespective of the anesthetic agent used to achieve EEG suppression. Yet anesthetic-induced EEG suppression is not a single physiologic state and is influenced by the drug used to produce suppression. When barbiturates are administered to the point of EEG suppression, a uniform depression in the CBF and CMR occurs throughout the brain. When suppression occurs during the administration of isoflurane and sevoflurane, the relative reductions in the CMR and CBF are more intense in the neocortex than in other portions of the cerebrum. Electrophysiologic responsiveness also varies. Cortical somatosensory evoked responses to median nerve stimulation can be readily recorded at doses of thiopental far in excess of those required to cause complete suppression of the EEG but are difficult to elicit at concentrations of isoflurane associated with a burst-suppression pattern (~1.5 minimum alveolar concentration [MAC]). In addition, the EEG characteristics of the burst-suppression states that occur just before complete suppression differ among anesthetic drugs. These differences may be of some relevance to discussions of differences in the neuroprotective potential of drugs that can produce EEG suppression.

Temperature. The effects of hypothermia on the brain have been reviewed in detail.[7] The CMR decreases by 6% to 7% per degree Celsius of temperature reduction. In addition to anesthetic drugs, hypothermia can also cause complete suppression of the EEG (at approximately 18°C-20°C). However, in contrast to anesthetic drugs, temperature reduction beyond that at which EEG suppression first occurs *does* produce a further decrease in the CMR (Fig. 11.5). This decrease occurs because anesthetic drugs reduce only the component of the CMR associated with neuronal function, whereas hypothermia decreases the rate of energy utilization associated with both electrophysiologic function and the basal component related to the maintenance of cellular integrity. Mild hypothermia preferentially suppresses the basal component of the CMR. The $CMRO_2$ at 18°C is less than 10% of normothermic control values, which may explain the brain's tolerance for moderate periods of circulatory arrest at these and colder temperatures.

Hyperthermia has an opposite influence on cerebral physiologic function. Between 37°C and 42°C, CBF and CMR increase. However, above 42°C, a dramatic reduction in cerebral oxygen consumption occurs, an indication of a threshold for a toxic effect of hyperthermia that may occur as a result of protein (enzyme) denaturation.

$PaCO_2$. CBF varies directly with $Paco_2$ (Fig. 11.6*A*), especially within the range of physiologic variation of $Paco_2$. CBF changes 1 to 2 mL/100 g/min for each 1 mm Hg change in $Paco_2$ around normal $Paco_2$ values. This response is attenuated at a $Paco_2$ less than 25 mm Hg. Under normal circumstances, the sensitivity of CBF to changes in $Paco_2$ ($\Delta CBF/\Delta Paco_2$) is positively correlated with resting levels of CBF. Accordingly, anesthetic drugs that alter resting CBF cause changes in the response of the cerebral circulation

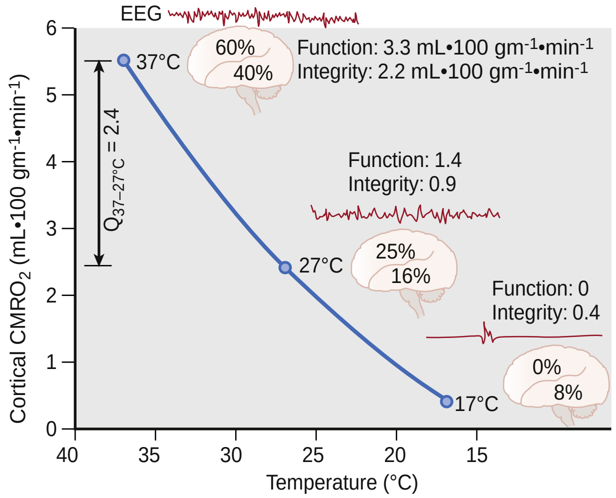

Fig. 11.5 Effect of temperature reduction on the cerebral metabolic rate of oxygen ($CMRO_2$) in the cortex. Hypothermia reduces both of the components of cerebral metabolic activity identified in Fig. 11.2—that associated with neuronal electrophysiologic activity (Function) and that associated with the maintenance of cellular homeostasis (Integrity). This is in contrast to anesthetics that alter only the functional component. The ratio of cerebral metabolic rate (CMR) at 37°C to that at 27°C, the Q10 ratio, is shown in the graph. Note that the $CMRO_2$ in the cortex (gray matter) is greater than global $CMRO_2$, considering the lower metabolic rate in white matter. *EEG*, Electroencephalogram. (Modified from Michenfelder JD. *Anesthesia and the brain: clinical, functional, metabolic, and vascular correlates*. New York: Churchill Livingstone; 1988.)

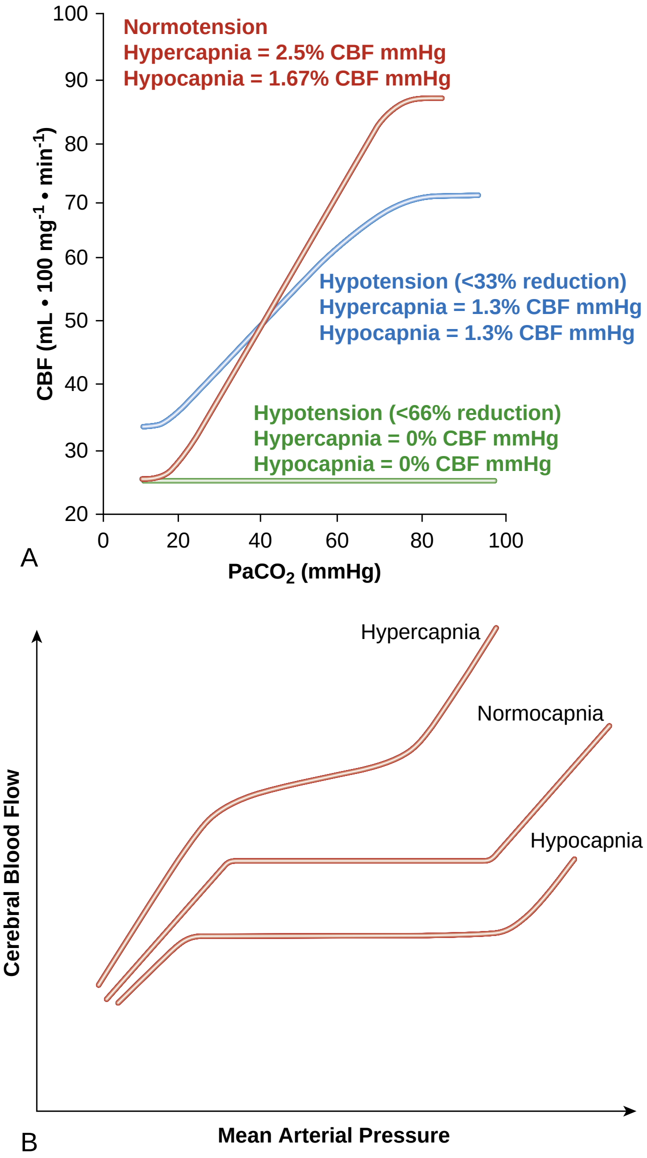

Fig. 11.6 *A,* Relationship between cerebral blood flow *(CBF)* and partial pressure of carbon dioxide *($Pa{CO_2}$)*. CBF increases linearly with increases in arterial $Pa{CO_2}$. Below a $Pa{CO_2}$ of 25 mm Hg, further reduction in CBF is limited. Similarly, the increase in CBF above a $Pa{CO_2}$ of approximately 75 to 80 mm Hg is also attenuated. The cerebrovascular responsiveness to $Pa{CO_2}$ is influenced significantly by blood pressure. With moderate hypotension (mean arterial pressure [MAP] reduction of <33%), the cerebrovascular responsiveness to changes in $Pa{CO_2}$ is attenuated significantly. With severe hypotension (MAP reduction of approximately 66%), CO_2 responsiveness is abolished. *B,* The effect of $Pa{CO_2}$ variation on cerebral autoregulation. Hypercarbia induces cerebral vasodilation and, consequently, the autoregulatory response to hypertension is less effective. By contrast, hypocapnia results in greater CBF autoregulation over a wider MAP variation. (Modified from Willie[8] and Rickards[9].)

to CO_2. The magnitude of the reduction in CBF caused by hypocapnia is more intense when resting CBF is increased (as might occur during anesthesia with volatile agents). Conversely, when resting CBF is reduced, the magnitude of the hypocapnia-induced reduction in CBF is decreased slightly. It should be noted that CO_2 responsiveness has been observed in normal brain during anesthesia with all the anesthetic drugs that have been studied.

The role of MAP in the CO_2 responsiveness of the cerebral circulation is further highlighted by the impact of modest and severe hypotension.[8] With the former, the increase in CBF attendant upon hypercarbia is significantly reduced, whereas hypocapnia-induced vasoconstriction is only modestly affected. When hypotension is severe, a cerebrovascular response to changes in $Pa{CO_2}$ is not observed (Fig. 11.6*A*). The level of $Pa{CO_2}$ also modulates cerebral autoregulation. With hypercarbia, cerebral autoregulatory response to hypertension is attenuated. By contrast, with the induction of hypocapnia, CBF is autoregulated over a wider MAP range (Fig 11.6*B*).[9]

The changes in CBF caused by $Pa{CO_2}$ are dependent on pH alterations in the extracellular fluid of the brain. NO, in particular NO of neuronal origin, is an important although not exclusive mediator of CO_2-induced vasodilation.[10] The vasodilatory response to hypercapnia is also mediated in part by prostaglandins. The changes in extracellular pH and CBF rapidly occur after $Pa{CO_2}$ adjustments because CO_2 freely diffuses across the cerebrovascular endothelium and the BBB. In contrast with *respiratory* acidosis, acute systemic *metabolic* acidosis has little immediate effect on CBF because the BBB excludes H^+ from the perivascular space. The CBF changes in response to alterations in $Pa{CO_2}$ rapidly occur, but they are not sustained. Despite the maintenance of an increased arterial pH, CBF returns toward normal over a period of 6 to 8 hours because the pH of CSF gradually returns to normal levels as a result of extrusion of bicarbonate (see Fig. 57.6). Consequently, a patient who has had a sustained period of hyperventilation or hypoventilation deserves special consideration. Acute restoration of a normal $Pa{CO_2}$ value will result in a significant CSF acidosis (after hypocapnia) or alkalosis (after hypercapnia). The

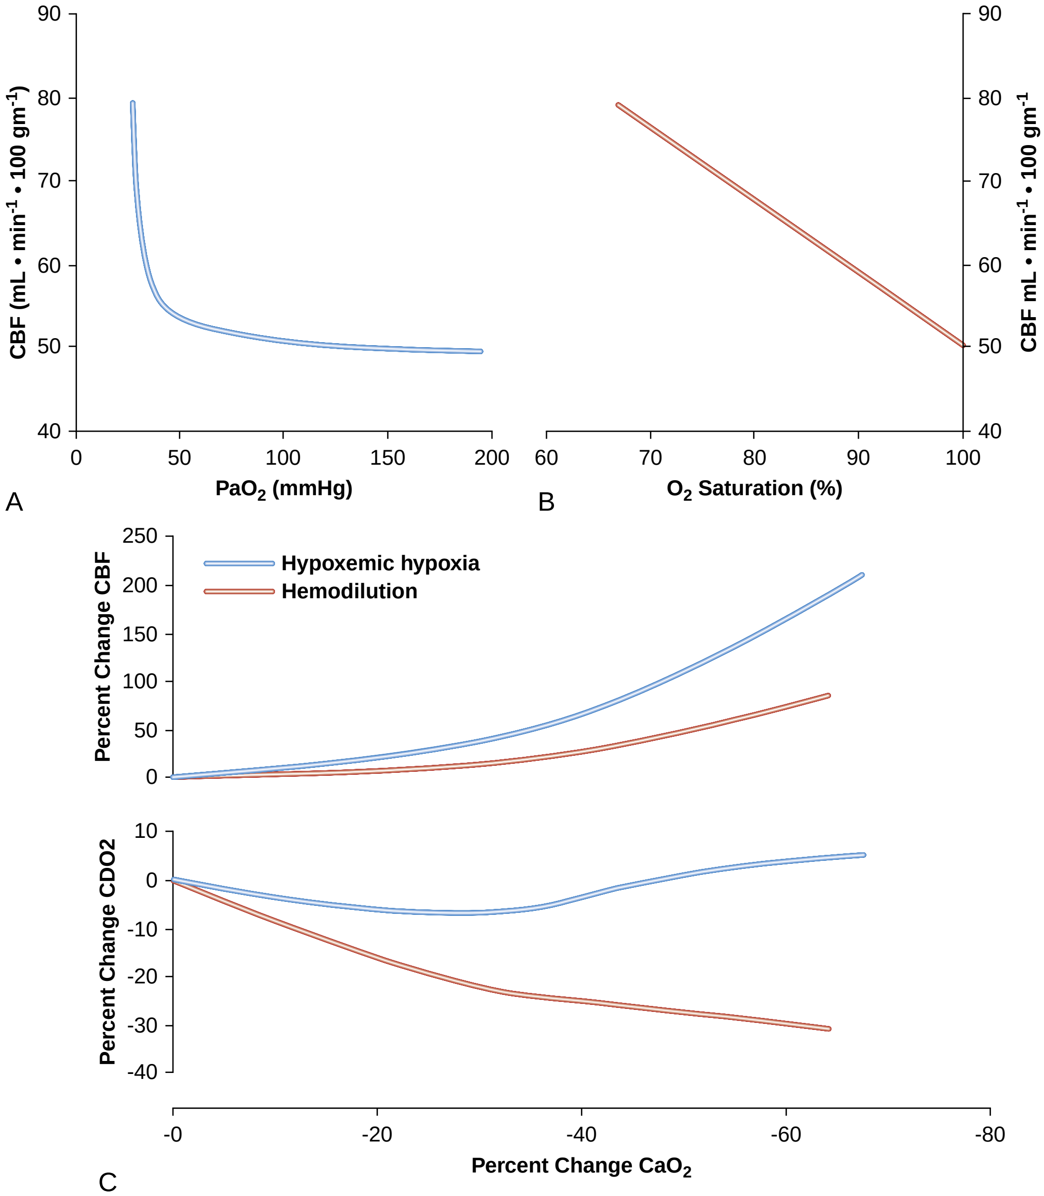

Fig. 11.7 (A) Relationship between cerebral blood flow *(CBF)* and partial pressure of oxygen *($Pa{O_2}$)*. Between the range of 60 and 200 mm Hg, $Pa{O_2}$ has little impact on CBF. A reduction in $Pa{O_2}$ to less than 60 mm Hg results in hemoglobin desaturation. There is significant cerebral vasodilation and a marked increase in CBF. (B) The relationship between hemoglobin saturation and CBF is inversely linear, with a gradual increase in CBF as saturation is decreased. (C) The impact of a reduction in cerebral oxygen delivery *(CDO_2)*, either by hypoxemic hypoxia or by hemodilution, is depicted. CBF increases significantly either with hypoxia or hemodilution; however, the CBF response is much greater with hypoxia *(upper panel)*. The total cerebral oxygen delivery is better maintained with hypoxia than hemodilution at a comparable level of arterial oxygen content *(CaO_2)* because of the greater CBF increase that occurs with the former. (Modified from Hoiland et al.[11] and Todd et al.[354,355].)

former results in increased CBF with a concomitant increase in ICP that depends on the prevailing intracranial compliance. The latter conveys a theoretic risk for ischemia.

$Pa{O_2}$. Changes in $Pa{O_2}$ from 60 to more than 300 mm Hg have little influence on CBF. A reduction in $Pa{O_2}$ below 60 mm Hg rapidly increases CBF (Fig. 11.7*A*). Below a $Pa{O_2}$ of 60 mm Hg, there is a rapid reduction in oxyhemoglobin saturation. The relationship between oxyhemoglobin saturation, as evaluated by pulse oximetry, and CBF is inversely linear (see Fig. 11.7*B*). The mechanisms mediating cerebral vasodilation during hypoxia may include neurogenic effects initiated by peripheral and neuraxial chemoreceptors, as well as local humoral influences. A reduction in arterial oxygen content, and therefore cerebral oxygen delivery, can be achieved either by a reduction in $Pa{O_2}$ (hypoxemic hypoxia) or by a reduction in hemoglobin concentration (anemia, hemodilution). Both hemodilution and hypoxemic hypoxia lead to cerebral vasodilation and an increase in CBF. Of the two variables, however, hypoxemic hypoxia is a far more potent variable in CBF augmentation than hemodilution. Cerebral oxygen delivery is better maintained during hypoxia when arterial content is equivalently reduced by hypoxia or hemodilution (see Fig. 11.7*C*). Deoxyhemoglobin plays a central role in hypoxia-induced increases in CBF by causing the release of NO and its metabolites, as well as ATP.[11] Hypoxia-induced opening of ATP-dependent K^+ channels in vascular smooth muscle leads to hyperpolarization and vasodilation. The rostral ventrolateral medulla (RVLM) serves as an oxygen sensor within the brain. Stimulation of the RVM by hypoxia results in an increase in CBF (but not CMR), and lesions of the RVLM suppress the magnitude of the CBF response to hypoxia. The response to hypoxia is synergistic with the hyperemia produced by hypercapnia and acidosis. At high PaO_2 values, CBF modestly decreases. At 1 atmosphere of oxygen, CBF is reduced by approximately 12%.

NEUROGENIC REGULATION OF CEREBRAL BLOOD FLOW

The cerebral vasculature is extensively innervated.[12] The density of innervation declines with vessel size, and the greatest neurogenic influence appears to be exerted on larger cerebral arteries. This innervation includes cholinergic (parasympathetic and nonparasympathetic), adrenergic (sympathetic and nonsympathetic), serotoninergic, and VIPergic systems of extraaxial and intraaxial origin. An extracranial sympathetic influence via the superior cervical ganglion, as well as parasympathetic innervation via the sphenopalatine ganglion, certainly exists in animals. The intraaxial pathways likely result from innervation arising from several nuclei, including the locus coeruleus, the fastigial nucleus, the dorsal raphe nucleus, and the basal magnocellular nucleus of Meynert. Evidence of the functional significance of neurogenic influences has been derived from studies of CBF autoregulation and ischemic injury. Hemorrhagic shock, a state of high sympathetic tone, results in less CBF at a given MAP than occurs when hypotension is produced with sympatholytic drugs. During shock, a sympathetically mediated vasoconstrictive effect shifts the lower end of the autoregulatory curve to the right. It is not clear what the relative contributions of humoral and neural mechanisms are to this phenomenon; however, a neurogenic component certainly exists because sympathetic denervation increases CBF during hemorrhagic shock. Moreover, sympathetic denervation produced by a blockade of the stellate ganglion can increase CBF in humans.[13] Activation of cerebral sympathetic innervation also shifts the ULA to the right and offers some protection against hypertension-induced increases in CBF (which can in certain circumstances lead to a breakdown of the BBB).[8] Experimental interventions that alter these neurogenic control pathways influence outcome after standardized ischemic insults, presumably by influences on vascular tone and therefore CBF. The nature and influence of such pathways in humans are not known, and their manipulation for the purposes of clinical management remains to be systematically investigated.

EFFECTS OF BLOOD VISCOSITY ON CEREBRAL BLOOD FLOW

Blood viscosity can influence CBF. Hematocrit is the single most important determinant of blood viscosity.[14] In healthy humans, variation of the hematocrit within the normal range (33%-45%) probably results in only modest alterations in CBF. Beyond this range, changes are more substantial. In anemia, cerebral vascular resistance is reduced and CBF increases. However, this may result not only from a reduction in viscosity but also as a compensatory response to reduced oxygen delivery.[15] Although arterial oxygen content can be reduced by both hypoxia and by hemodilution, the increase in CBF that accompanies hypoxia is of a greater magnitude than that by hemodilution induced reduction in oxygen delivery.[11] The effect of a reduction in viscosity on CBF is more important with focal cerebral ischemia, a condition in which vasodilation in response to impaired oxygen delivery is probably already maximal. In this situation, reducing viscosity by hemodilution increases CBF in the ischemic territory. In patients with focal cerebral ischemia, a hematocrit of 30% to 34% will result in optimal delivery of oxygen. However, manipulation of viscosity in patients with acute ischemic stroke is not of benefit in reducing the extent of cerebral injury. Therefore, viscosity is not a target of manipulation in patients at risk as a result of cerebral ischemia, with the possible exception of those with hematocrit values higher than 55%.

CARDIAC OUTPUT

The conventional view of cerebral hemodynamics is that perfusion pressure (MAP or CPP) is the primary determinant of CBF and that the influence of cardiac output is limited. More recent data suggest that cardiac output impacts cerebral perfusion. In several investigations in which central blood volume was modulated, either reduced by application of lower body negative pressure, or increased by the infusion of fluid, a linear relationship between cardiac output and CBF, as measured as middle cerebral artery flow velocity (MCAfv) by transcranial Doppler, was clearly demonstrated.[8,16-20] An analysis of the pooled data from these investigations indicates that a reduction in cardiac output of approximately 30% leads to a decrease in CBF by about 10%.[21] In patients undergoing hip arthroplasty under hypotensive epidural anesthesia, the administration of epinephrine led to a maintenance of CBF even though the MAP was below the LLA.[22] Presumably, this maintenance of CBF was due to an epinephrine-induced increase in cardiac output. An association between CO and CBF has also been observed in acute stroke, subarachnoid hemorrhage-induced vasospasm, and sepsis. However, the CO–CBF relationship has not been demonstrated uniformly; in fact, augmentation of CO does not increase CBF in several disease states, including traumatic head injury, neurologic surgery, and cardiac surgery.[21] Collectively, the available data suggest that CO does influence CBF and that this effect may be of particular relevance in situations in which circulating volume is reduced and in shock states.

AN INTEGRATED CONTEMPORARY VIEW OF CEREBRAL AUTOREGULATION

The conventional view of cerebral autoregulation is that CBF is held constant as MAP increases between the lower limit and ULA. The currently available data, however, indicate that this view is now outmoded and is in need of revision. As discussed previously, CBF and the cerebral vasculature are influenced by a variety of variables. Clearly, MAP (perfusion pressure) is a major determinant of CBF. Cardiac output is increasingly being recognized as an important determinant of CBF. Cardiac output in turn is dependent on adequate circulatory volume, cardiac preload, contractility, afterload, and heart rate and rhythm. The presence of cardiovascular disease, in particular congestive heart failure, will limit the capacity of autoregulatory mechanisms to maintain CBF in response to hypotension. Arterial blood gas tensions affect vasomotor tone, and both hypercarbia and hypoxia attenuate autoregulation. The contribution of the sympathetic nervous system is of importance in the cerebrovascular response to hypertension. At the same time, sympathetic nerves reduce the vasodilatory capacity of the cerebral vessels during hypotension. A variety of medications can impact autoregulation, either through modulation of sympathetic nervous system activity (β-antagonists, α_2-agonists) or by direct reduction of vasomotor tone (calcium channel antagonists, nitrates, angiotensin receptor blockers, angiotensin converting enzyme [ACE] inhibitors). Anesthetics modulate autoregulation by a number of means, including suppression of metabolism, alteration of neurovascular coupling to a higher flow–metabolism ratio, suppression of autonomic neural activity, and by direct effect on cerebral vasomotor tone, and alteration of cardiac function and systemic circulatory tone.

Cerebrovascular tone and CBF are therefore under the control of a complex regulatory system (Fig. 11.8). Given the multitude of factors that determine the capacity of the cerebral circulation to respond to changes in perfusion pressure, the premise that cerebral autoregulation is static is now untenable. Rather, cerebral autoregulation should be viewed as a dynamic process and that the morphologic form of the autoregulatory curve is the result of the integration of all the variables that affect cerebrovascular tone in an interdependent manner.[8,23] Therefore, a continuum of vascular responsiveness in both the lower and upper limits and in the plateau probably exists as the ability of the cerebrovascular bed to dilate or constrict is exhausted. In a review of the available data from investigations in humans, the range of pressures that defined the LLA spanned from 33 mm Hg to as high as 108 mm Hg.[5]

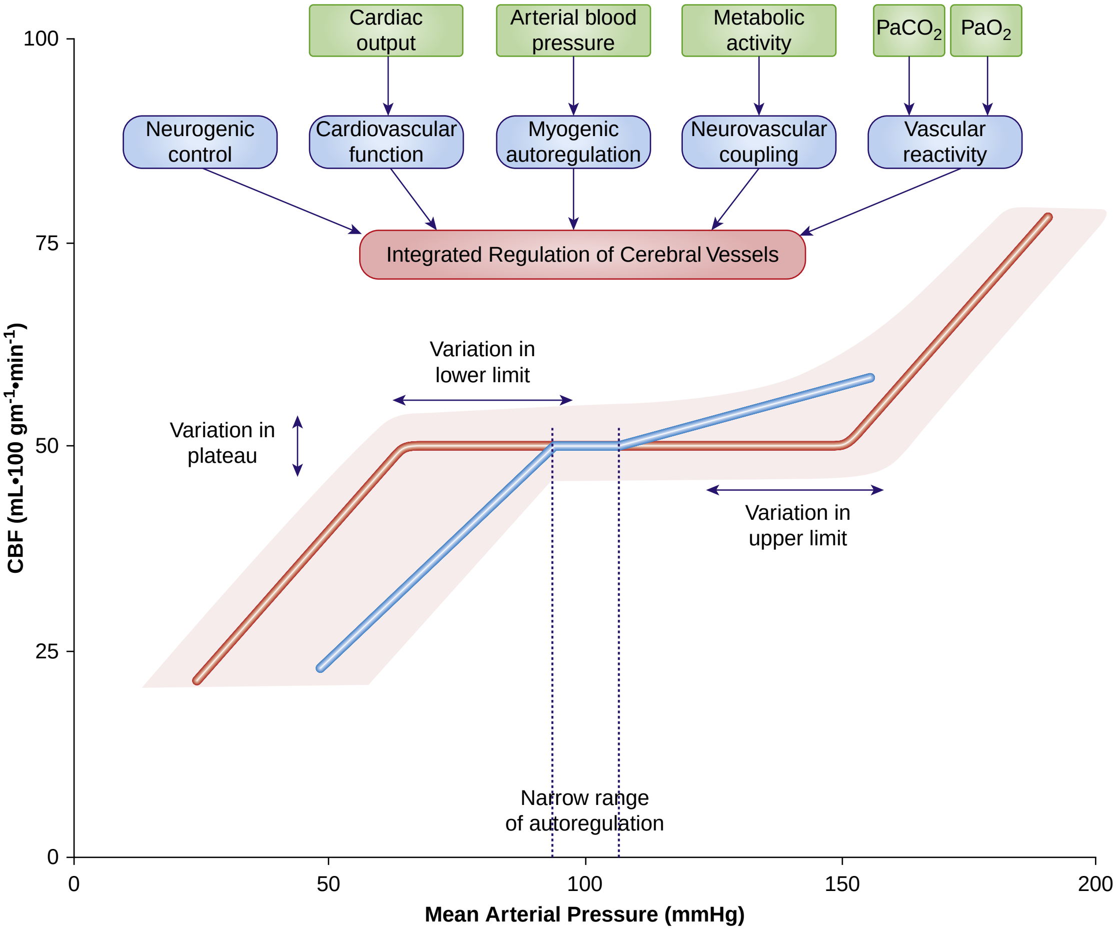

Fig. 11.8 Integrative regulation of cerebral blood flow *(CBF)*. The conventional view of cerebral autoregulation is that CBF is maintained constant with a variation in mean arterial pressure (MAP) of 65 to 150 mm Hg. A more contemporary view is that cerebral autoregulation is a dynamic process that is under the influence of a number of variables including myogenic autoregulation, neurovascular coupling, arterial CO_2 and O_2 tensions, autonomic (neurogenic) activity, and cardiovascular function. Anesthetic agents in particular affect autoregulation at multiple levels: suppression of metabolism, alteration in arterial blood gas tensions, direct cerebral vasodilation, suppression of autonomic activity, and modulation of cardiovascular function. Therefore, CBF at any given moment is a product of the composite of these variables. There is considerable variation in lower and upper limits as well as the plateau of the autoregulatory curve. The conventional autoregulatory curve is depicted in red. The red shaded area represents the range of variation in CBF. The autoregulatory curve depicted in blue was derived from 48 healthy human subjects. In that group, the lower limit of autoregulation was approximately 90 mm Hg and the range over which CBF remained relatively constant was only 10 mm Hg. *$Pa{CO_2}$*, Arterial partial pressure of carbon dioxide; *$Pa{O_2}$*, arterial partial pressure of oxygen. (Modified from Tan et al.,[24] Willie et al.,[8] and Meng and Gelb.[23])

In healthy humans subjected to lower body negative pressure to reduce central blood volume and to reduce blood pressure, the autoregulatory plateau spanned a range of only 10 mm Hg (± 5 mm Hg from baseline)[24] as opposed to a range of 100 mm Hg in the once conventional representations of autoregulation. Above and below this narrow plateau, CBF was pressure passive. Even within this narrow plateau, a modest increase in CBF with increases in blood pressure is observable—that is, the plateau is not flat. The slope of the percentage change in MAP to percentage change in CBF relationship has been demonstrated to be 0.81 ± 0.77 with induction of hypotension and 0.21 ± 0.47 with the induction of hypertension. These data are consistent with the premise that the capacity of the cerebral circulation to adapt to increases in blood pressure is considerably greater than adaptation to hypotension.[8] Based on these more recent observations, the conventional view of autoregulation is probably not applicable to most subjects, and a revision of the framework of cerebral circulatory control along the lines of recent data is needed.[8,23] In this respect, it is the view of the authors that cerebral autoregulation should be accurately represented by a family of autoregulatory curves rather than a single static curve (see Fig. 11.8). In these dynamic autoregulatory curves, there is considerable heterogeneity in the LLA and ULA, as well as in the limits and slope of the plateau.

Clinical implications: Maintenance of cerebral perfusion is essential, and identification of a target range of MAP in individual patients is a key part of anesthetic management. Given the substantial variability in cerebral autoregulatory capacity, it may be difficult to identify the target range based on an LLA in most patients. Selection of the target range based on the baseline pressure, after due consideration of comorbid conditions that may impact cerebrovascular and cardiovascular performance, may be preferable. In attempts to maintain adequate perfusion pressure, the traditional approach of systemic vasoconstriction, for example with α_1-agonists, is reasonable. However, the adequate maintenance of circulatory volume and of cardiac output should also be considered; administration of agents that can also increase cardiac output may be of value. This may be of particular relevance in patients with compromised cardiac function.

VASOACTIVE DRUGS

Many drugs with intrinsic vascular effects are used in contemporary anesthetic practice, including both anesthetic drugs and numerous vasoactive drugs specifically used for hemodynamic manipulation. This section deals with the latter. The actions of anesthetics are discussed in the "Effects of Anesthetics on Cerebral Blood Flow and Cerebral Metabolic Rate" section.

Systemic Vasodilators

Most drugs used to induce hypotension, including sodium nitroprusside, nitroglycerin, hydralazine, adenosine, and calcium channel blockers (CCBs), also cause cerebral vasodilation. As a result, CBF either increases or is maintained at pre-hypotensive levels. In addition, when hypotension is induced with a cerebral vasodilator, CBF is maintained at lower MAP values than when induced by either hemorrhage or a noncerebral vasodilator. In contrast to direct vasodilators, the ACE inhibitor enalapril does not have any significant effect on CBF. Anesthetics that simultaneously vasodilate the cerebral circulation cause increases in cerebral blood volume (CBV) with the potential to increase ICP. The effects of these anesthetics on ICP are less dramatic when hypotension is slowly induced, which probably reflects the more effective interplay of compensatory mechanisms (i.e., shifts in CSF and venous blood) when changes occur more slowly.

Catecholamine Agonists and Antagonists

Numerous drugs with agonist and antagonist activity at catecholamine receptors (α_1, α_2, β_1, β_2, and dopamine) are in common use. The effects of these vasoactive drugs on cerebral physiology are dependent on basal arterial blood pressure, the magnitude of the drug-induced arterial blood pressure changes, the status of the autoregulation mechanism, and the status of the BBB. A drug may have direct effects on cerebral vascular smooth muscle or indirect effects mediated by the cerebral autoregulatory response to changes in systemic blood pressure (or both types of effects). When autoregulation is preserved, increases in systemic pressure should increase CBF if basal blood pressure is outside the limits of autoregulation. When basal pressure is within the normal autoregulatory range, an increase in systemic arterial pressure does not significantly affect CBF because the normal autoregulatory response to a rising MAP entails cerebral vasoconstriction (i.e., an increase in cerebral vascular resistance) to maintain a constant CBF. When autoregulation is defective, CBF will vary in direct relation to arterial pressure. The information in the following paragraphs and in Table 11.2 emphasizes data obtained from investigations of vasopressors in intact preparations, and gives priority to the results obtained in humans and higher primates.

α_1-Agonists. Will the administration of α_1-agonists (phenylephrine, norepinephrine) reduce CBF?

Studies in humans and nonhuman primates do not confirm this concern. Intracarotid infusions of norepinephrine in doses that significantly increase the MAP result in no change in CBF. Norepinephrine can increase CBF, but such increases might occur if autoregulation were defective or its limit exceeded. β-Mimetic drugs (norepinephrine has β_1 activity) may cause activation of cerebral metabolism[25] with a coupled increase in CBF. This effect is more apparent when these drugs can gain greater access to the brain parenchyma via a defective BBB (see Table 11.2). Administration of phenylephrine to patients undergoing cardiopulmonary bypass does not decrease CBF. In spinal cord–injured patients with relative hypotension, the administration of the α_1-agonist midodrine increased perfusion pressure and increased flow velocity in the middle cerebral artery (MCA) and the posterior cerebral artery.[26] In healthy patients,[27] and in those undergoing surgery in the beach chair position,[28] the administration of phenylephrine maintains or augments MCAfv. Collectively, these data suggest that norepinephrine and phenylephrine maintain cerebral perfusion.

TABLE 11.2 Best Estimates of the Influence of Pure Catecholamine Receptor Agonists and Specific Pressor Substances on Cerebral Blood Flow and Cerebral Metabolic Rate

Agonist	Cerebral Blood Flow	Cerebral Metabolic Rate
PURE		
α_1	0/–	0
α_2	–	–
β	+	+
β (BBB open)	+++	+++
Dopamine	++	0
Dopamine (high dose)	–	?0
Fenoldopam	–	?0
MIXED		
Norepinephrine	0/–	0/+
Norepinephrine (BBB open)	+	+
Epinephrine	+	+
Epinephrine (BBB open)	+++	+++

The number of symbols indicates the magnitude of the effect.
Where species differences occurred, data from primates were given preference. See text for complete discussion.
BBB, Blood-brain barrier; +, increase; –, decrease; 0, no effect.

The traditional view that CBF can be maintained by the administration of α_1-agonists without any adverse effect on cerebral oxygenation has been challenged. In anesthetized patients,[29-31] phenylephrine administration by bolus modestly reduced regional cerebral oxygen saturation (rSO_2), measured by near-infrared oximetry. Ephedrine, although increasing arterial blood pressure to a similar extent as phenylephrine, did not reduce rSO_2, presumably because of its ability to maintain cardiac output. In human volunteers, a norepinephrine-induced increase in arterial blood pressure slightly reduced MCAfv and cerebral oxygen saturation (Sco_2) and $SjVo_2$.[32] By contrast, although phenylephrine decreased rSO_2, MCAfv was increased and $SjVo_2$ was unchanged.[33] These data have led to the question of whether phenylephrine and norepinephrine administration negatively impact cerebral oxygenation. Several factors argue against this possibility.[34] The first concern is methodology. Near-infrared spectroscopy (NIRS) measures oxygenated and deoxygenated blood in a defined region of brain and is a composite of arterial, capillary, and venous blood. Vasopressors affect both arterial and venous tone. Even a minor change in the volume of arterial and venous volumes within the region of the brain can affect the rSO_2 measurement. Moreover, extracranial contamination is a significant component of the rSO_2 values reported by the currently available NIRS monitors.[35] This contamination is more important than the slight reduction in Sco_2 observed in these investigations. In the absence of direct measurement of brain tissue oxygenation, a modest reduction in Sco_2 in the face of increasing arterial blood pressure cannot be taken as evidence of impairment of cerebral oxygenation. In addition, phenylephrine did not decrease $SjVo_2$, a more global measurement of cerebral oxygenation. Although norepinephrine decreased $SjVo_2$ by approximately 3% (a mild reduction at best), its administration has been previously shown to increase the $CMRO_2$. Finally, the minor reduction in rSO_2 effected by phenylephrine is no longer apparent when an increase in the $CMRO_2$ is concurrent. Phenylephrine apparently does not prevent an increase in CBF when such an increase is warranted by increased brain metabolism.

These studies were conducted in patients with a normal central nervous system (CNS). Although unlikely, the concern is that α_1-agonists might reduce cerebral perfusion in the injured brain. In patients with a head injury, the administration of phenylephrine increased CPP and did not reduce regional CBF.[36] Transient changes may occur in CBF and rSO_2 (on the order of 2-5 minutes) in response to bolus doses of phenylephrine; however, with a continuous infusion, α_1-agonists have little direct influence on CBF and cerebral oxygenation in humans.[34] Thus maintenance of CPP with these vasopressors does not have an adverse effect on the brain.

α_2-Agonists. α_2-Agonists have both analgesic and sedative effects. This class of drugs includes dexmedetomidine and clonidine, with the latter being a significantly less specific and less potent α_2-agonist. Two investigations in human volunteers have confirmed the ability of dexmedetomidine to decrease CBF. Dexmedetomidine dose-dependently decreased MCAfv, with the maximum reduction being approximately 25%.[37] Dexmedetomidine (1 μg/kg loading dose and infusion at either 0.2 or 0.6 μg/kg/hr) decreased CBF by approximately 30%[38] in healthy human volunteers. In both these investigations, the CMR was not measured; whether the reduction in CBF was due to a direct vasoconstrictor activity of dexmedetomidine or to suppression of the CMR with a corresponding reduction in CBF is not clear. In a more recent study of dexmedetomidine during which both MCAfv and the CMR were measured in healthy humans, dexmedetomidine decreased MCAfv in parallel with a reduction in the CMR.[39] Similarly, in healthy patients[40] and those with traumatic brain injury[41] undergoing sedation with dexmedetomidine, the reduction in CBF was matched by a parallel reduction in CMR. Thus the effects of dexmedetomidine on CBF were primarily mediated by its ability to suppress the CMR; the reduction in CBF is commensurate with the reduction in CMR, and there is no evidence that dexmedetomidine causes cerebral ischemia. However, the well-known effect of dexmedetomidine in decreasing arterial blood pressure merits careful consideration if used in patients who are critically dependent on collateral perfusion pressure, especially in the recovery phase of an anesthetic.

β-Agonists. β-receptor agonists, in small doses, have little direct effect on the cerebral vasculature. In larger doses and in association with physiologic stress, they can cause an increase in the CMR with an accompanying increase in CBF. The β_1-receptor is probably the mediator of these effects. In doses that do not result in substantial changes in the MAP, intracarotid epinephrine does not change CBF in nonanesthetized humans. However, with larger doses that lead to an increase in the MAP, both CBF and $CMRO_2$ can increase by approximately 20%. A recent investigation has demonstrated that the administration of epinephrine in patients undergoing surgery under hypotensive epidural anesthesia can increase MCAfv, presumably by augmenting cardiac output (as discussed previously).[22]

Dobutamine can increase CBF and CMR by 20% and 30%, respectively. Dobutamine can increase CBF independent of its effect on blood pressure; the increase in CBF has been attributed to the augmentation of cardiac output by dobutamine.[36]

Evidence suggests that a defect in the BBB enhances the effect of β-agonists.[42] Intracarotid norepinephrine, which does not normally affect CBF and CMR, increases CBF and CMR when BBB permeability is increased with hypertonic drugs. Epinephrine caused an elevation in the $CMRO_2$, but only when the BBB was made permeable.[42] These observations beg the interpretation that β-agonists will increase CBF and CMR *only* when the BBB is injured. However, when epinephrine was given in doses that did not significantly increase the MAP, increases in CBF and CMR occurred. Accordingly, BBB injury may exaggerate but is not a necessary condition in humans for the occurrence of β-mediated increases in CBF and CMR.

β-Blockers. β-Adrenergic blockers either reduce or have no effect on CBF and CMR. In two investigations in humans, propranolol, 5 mg intravenously,[43] and labetalol, 0.75 mg/kg intravenously,[44] had no effect on CBF and cerebral blood flow velocity (CBFV), respectively. Modest reductions in CBF occur after the administration of labetalol to patients undergoing craniotomy who become hypertensive during emergence from anesthesia. Esmolol shortens seizures induced by electroconvulsive therapy (ECT), which suggests that esmolol does cross the normal BBB. Catecholamine levels at the time of β-blocker administration or the status of the BBB (or both) may influence the effect of these drugs. β-Adrenergic blockers are unlikely to have adverse effects on patients with intracranial pathology, other than effects secondary to changes in perfusion pressure.

Dopaminergic agents. Dopamine can be used for the treatment of hemodynamic dysfunction. It also augments the function of the normal cardiovascular system when an increase in the MAP is desired as an adjunct to the treatment of focal cerebral ischemia, especially in the setting of vasospasm. Nonetheless, its effects on CBF and CMR have not been defined with certainty. The likely predominant effect of dopamine in the normal cerebral vasculature, when administered in small doses, is probably slight vasodilation with a minimal change in the CMR.[45] Increased CMR in discrete regions of the brain, such as the choroid plexus and basal ganglia, can occur. However, overall cortical blood flow is not influenced. Vasoconstriction of the cerebral circulation is not observed even when dopamine is administered in doses of up to 100 μg/kg/min.[45] Fenoldopam is a dopamine agonist with activity at the DA_1-receptor and α_2-receptor. The administration of fenoldopam leads to systemic vasodilation and a decrease in arterial blood pressure. In humans, fenoldopam decreased systemic blood pressure to a level that was above the LLA; however, a modest (≈15%) reduction was observed in CBF that did not increase to normal levels when systemic blood pressure was supported.[46] The reason for the reduction of CBF is not clear.

Calcium channel blockers. CCBs are frequently used to treat acute hypertension in the neurologically injured patient population. Cerebral vessels are richly endowed with calcium channels, in particular the L-type calcium channel. CCBs therefore induce vasodilation of the pial and cerebral arteries. In healthy humans, intravenous administration of nimodipine does not change CBF; however, when the slight decrease in MAP and changes in $Paco_2$ are taken into consideration, CBF increased by approximately 5% to 10%.[47] CMR and CO_2 reactivity are maintained. Nimodipine in human subjects does, however, blunt autoregulation moderately.[48] Intraarterial nimodipine for the treatment of cerebral vasospasm after subarachnoid hemorrhage increased regional CBF significantly provided MAP was maintained, indicating that nimodipine is a cerebral vasodilator.[49]

Nicardipine is perhaps the most commonly used CCB for perioperative blood pressure control because of its short half-life and easy titratability. Nicardipine is a modest cerebral vasodilator and has repeatedly been shown to increase CBF or CBFV while reducing systemic MAP. Cerebral CO_2 reactivity appears to be well preserved in the presence of nicardipine.[50,51]

Clevidipine is a third generation dihydropyridine CCB that has an ultrashort half-life because it undergoes rapid esterase-mediated metabolism. Its use in both the cardiac and neurologic patient populations has increased significantly given its rapid titratability. In healthy volunteers, clevidipine did not increase MCAfv. However, a substantial reduction in MAP of approximately 25% occurred.[52] The lack of increase in MCAfv in the face of hypotension suggests that clevidipine is a cerebral vasodilator and, like nicardipine, probably attenuates autoregulation to a moderate extent. CO_2 reactivity is preserved.

The available data indicate that CCBs are moderate cerebral vasodilators. Their net impact on CBF is therefore dependent on the extent of systemic vasodilation and MAP. When MAP is maintained, increases in CBF should be expected.

Angiotensin II, Angiotensin-Converting Enzyme Inhibitors, and Angiotensin Receptor Antagonists

There has been a renaissance of the use of angiotensin II (AII) for the treatment of vasodilatory shock that is refractory to conventional vasopressor agents. In these shock states, AII increased MAP and reduced the need for other vasopressors including norepinephrine and vasopressin. The acute effect of AII on the cerebral circulation has received only modest attention. Acute administration of AII increases cerebral microvascular constriction without affecting CBF; this effect precedes its impact on blood pressure. However, AII attenuates regional hyperemia that occurs with an increase in regional metabolism, thereby adversely impacting neurovascular coupling.[53] Given that CBF is maintained in the face of increased blood pressure, autoregulation and CO_2 responsivity appear to be maintained.[54]

Both ACE inhibitors and angiotensin-receptor blockers (ARBs) are commonly used to treat hypertension. In the surgical setting and in the neurocritical care unit, these drugs are administered to control arterial blood pressure acutely. ACE inhibitors and ARBs reduce arterial blood pressure when hypertension is present. However, they do not affect resting CBF, and autoregulation is maintained.[55] However, acute administration of ACE inhibitors and ARBs decreases the LLA (left shift of the autoregulatory curve in experimental animals);[56] the significance of this finding in humans is not clear. In patients with acute stroke, ACE inhibitors and ARBs reduce arterial blood pressure but do not acutely affect CBF.[57,58] Apparently, these drugs do not reduce CBF when arterial blood pressure is modestly decreased.

AGE

The loss of neurons is progressive in the normally aging brain from young adulthood to advanced age. There is approximately 10% neuronal loss in healthy aged brain.[59] The loss of myelinated fibers results in reduced white matter volume.[60] By contrast, the loss of synapses in the aged brain is considerably greater. The majority of excitatory synapses in the brain are on dendritic spines. Dendrite branching and volume decrease progressively, and the number of dendritic spines is reduced by approximately 25% to 35%.[60] Concomitant with the loss of neuropil, both CBF and $CMRO_2$ decrease by 15% to 20% at the age of 80 years.[61] Cerebral circulatory responsiveness to changes in Paco_2 and to hypoxia are slightly reduced in the healthy aged brain.[4,62]

Effects of Anesthetics on Cerebral Blood Flow and Cerebral Metabolic Rate

This section discusses the effects of anesthetic drugs on CBF and CMR. It includes limited mention of the influences on autoregulation, CO_2 responsiveness, and CBV. Effects on CSF dynamics, the BBB, and epileptogenesis are discussed later in the chapter.

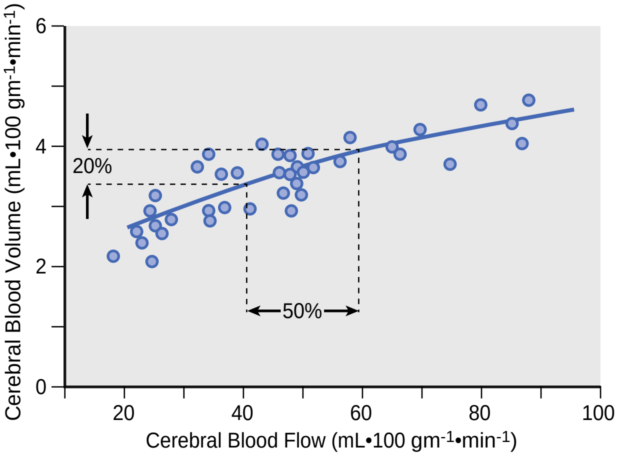

Fig. 11.9 Relationship between cerebral blood flow (CBF) and cerebral blood volume (CBV). Although a linear relationship exists between CBF and CBV, the magnitude of the change in CBV for a given change in CBF is considerably less. An increase in CBF of 50% results in a change in CBV of only 20%.

In the practice of neuroanesthesia, the manner in which anesthetic drugs and techniques influence CBF receives prime attention. The rationale is twofold. First, the delivery of energy substrates is dependent on CBF, and modest alterations in CBF can influence neuronal outcome substantially in the setting of ischemia. Second, control and manipulation of CBF are central to the management of ICP because as CBF varies in response to vasoconstrictor-vasodilator influences, CBV varies with it.[63] With respect to ICP, CBV is the more critical variable. In the normal brain, CBV is approximately 5 mL/100 g of brain, and over a Paco_2 range of approximately 25 to 70 mm Hg, CBV changes by approximately 0.049 mL/100 g for each 1 mm Hg change in Paco_2. In an adult brain weighing approximately 1400 g, this change can amount to 20 mL in total CBV for a Paco_2 range of 25 to 55 mm Hg. Because CBV is more difficult to measure than CBF few data exist, especially in humans.

Although CBV and CBF usually vary in parallel, the magnitude of change in CBV is less than the magnitude of change in CBF (Fig. 11.9). In addition, CBV and CBF vary independently under some circumstances. During cerebral ischemia, for example, CBV increases, whereas CBF is reduced significantly. Autoregulation normally serves to prevent MAP-related increases in CBV. In fact, as the cerebral circulation constricts to maintain a constant CBF in the face of an increasing MAP, CBV actually decreases. When autoregulation is impaired or its upper limit (≈150 mm Hg) is exceeded, CBF and CBV then increase in parallel as arterial blood pressure increases (see Fig. 11.8). A decreasing MAP results in a progressive increase in CBV as the cerebral circulation dilates to maintain constant flow, and exaggerated increases in CBV occur as the MAP decreases to less than the LLA. In normal subjects, the initial increases in CBV do not increase ICP because there is latitude for compensatory adjustments by other intracranial compartments (e.g., translocation of venous blood and CSF to extracerebral vessels and the spinal CSF space, respectively). When

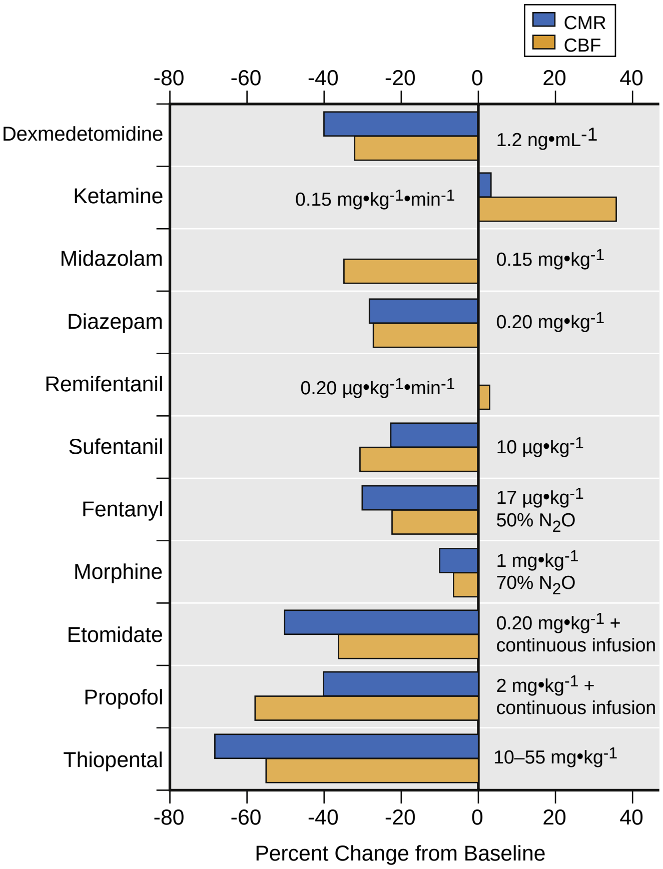

Fig. 11.10 Changes in cerebral blood flow *(CBF)* and the cerebral metabolic rate of oxygen ($CMRO_2$) caused by intravenous anesthetic drugs. The data are derived from human investigations and are presented as percent change from nonanesthetized control values. Dexmedetomidine CMR values were determined on a background of 0.5% isoflurane anesthesia (see the text for details). No data for the $CMRO_2$ effects of midazolam in humans are available. *CMR*, Cerebral metabolic rate. (Data from references 25, 47–59.)

intracranial compliance* is reduced, an increase in CBV can cause herniation or sufficiently reduce CPP to cause ischemia.

INTRAVENOUS ANESTHETIC DRUGS

The action of most intravenous anesthetics leads to parallel reductions in CMR and CBF. Ketamine, which causes an increase in the CMR and CBF, is the exception. The effects of selected intravenous anesthetic drugs on human CBF are compared in Fig. 11.10.[38,65-77]

Intravenous anesthetics maintain neurovascular coupling, and consequently changes in CBF induced by intravenous anesthetics are largely the result of the effects on the CMR with parallel (coupled) changes in CBF. Intravenous anesthetics have direct effects on vascular tone. Barbiturates, for example, cause relaxation of isolated cerebral vessels in vitro. However, *in vivo*, barbiturates suppress CMR, and the net effect at the point of EEG suppression is vasoconstriction and a substantial decrease in CBF.[78] In general, autoregulation and CO_2 responsiveness are preserved during the administration of intravenous anesthetic drugs.

Barbiturates

A dose-dependent reduction in CBF and CMR occurs with barbiturates. With the onset of anesthesia, both CBF and $CMRO_2$ are reduced by approximately 30%. When large doses of thiopental cause complete EEG suppression, CBF and CMR are reduced by approximately 50% to 60%.[78,79] Further increases in the barbiturate dose have no additional effect on the CMR.[78] These observations suggest that the major effect of nontoxic doses of depressant anesthetics is a reduction in the component of cerebral metabolism that is linked to electrical brain function (e.g., neurophysiologic activity) with only minimal effects on the second component, which is related to cellular homeostasis (see Fig. 11.2).

Tolerance to the CBF and CMR effects of barbiturates may quickly develop.[80] In patients with severe head injury in whom *barbiturate coma* was maintained for 72 hours, the blood concentration of thiamylal required to maintain EEG burst suppression was observed to be increased by the end of the first 24 hours and continued to increase over the next 48 hours.[81] During deep pentobarbital anesthesia, autoregulation and CO_2 responsiveness are maintained.

Propofol

The effects of propofol (2,6-diisopropylphenol) on CBF and CMR are similar to those of barbiturates. Both CBF and CMR decrease after the administration of propofol in humans.[82] In healthy volunteers, surgical levels of propofol reduced regional CBF by 53% to 79% in comparison with the awake state.[83,84] Cerebral glucose metabolism in volunteers was evaluated by positron-emission tomography (PET) before and during infusion of propofol to the point of unresponsiveness, and resulted in a decrease of the whole-brain metabolic rate of 48% to 58%, with limited regional heterogeneity.[85] When compared with isoflurane-fentanyl or sevoflurane-fentanyl anesthesia, a combination of propofol and fentanyl decreased subdural pressure in patients with intracranial tumors and decreased the arteriovenous oxygen content difference ($AVDO_2$).[86] Collectively, these investigations in human subjects indicate that propofol effects reductions in the CMR and secondarily decreases CBF, CBV, and ICP.

Both CO_2 responsiveness and autoregulation are preserved in humans during the administration of propofol,[87,88] even when administered in doses that produce burst suppression of the EEG.[89] The magnitude of the reduction in CBF during hypocapnia is decreased during propofol administration. This effect is probably due to the cerebral vasoconstriction induced by suppression of CMR, which limits further hypocapnia-mediated vasoconstriction.

Etomidate

The effects of etomidate on CBF and CMR are also similar to those of barbiturates. Roughly parallel reductions in CBF and CMR occur in humans,[65,90] and in general, they are accompanied by progressive suppression of the EEG.

---

*Note a well-entrenched misuse of terminology.[64] The "compliance" curve that is commonly drawn to describe the ICP-volume relationship (see Fig. 57-3) actually depicts the relationship $\Delta P/\Delta V$ (elastance) and not $\Delta V/\Delta P$ (compliance). References to "reduced compliance" in this text would more correctly be rendered as "increased elastance." However, because the existing literature most commonly uses the "compliance" terminology, the authors have left the misuse uncorrected herein.

Induction of anesthesia with either thiopental or etomidate resulted in a similar reduction in MCAfv by approximately 27%.[91] The changes in CBF and CMR are substantial. Etomidate, 0.2 mg/kg, reduced CBF and CMR by 34% and 45%, respectively, in adults.[65] As is the case with barbiturates, no further reduction in the CMR occurs when additional drug is administered beyond a dose sufficient to produce EEG suppression. Although this latter phenomenon has not been demonstrated in humans, etomidate has been demonstrated to reduce ICP only when EEG activity is well preserved; etomidate is ineffective in reducing ICP when EEG activity is suppressed in head injured patients.[92] The global CMR suppression attainable with etomidate is slightly less profound than that achieved with isoflurane and barbiturates. This finding is consistent with the observation that unlike barbiturates, which cause CMR suppression throughout the brain, the CMR suppression caused by etomidate is regionally variable and occurs predominantly in forebrain structures.

Etomidate is effective in reducing ICP without causing a reduction in CPP in patients with intracranial tumors[93] and patients with head injuries.[94] However, the administration of etomidate resulted in an exacerbation of brain tissue hypoxia and acidosis in patients in whom the MCA was temporarily occluded during surgery.[95] Additional concerns regarding the occurrence of adrenocortical suppression caused by enzyme inhibition and renal injury caused by the propylene glycol vehicle[96] will probably preclude more than episodic use.

Reactivity to CO_2 is preserved in humans during the administration of etomidate.[65,90] Autoregulation has not been evaluated. Myoclonus and epileptogenesis are discussed in the section, "Epileptogenesis."

Narcotics

Inconsistencies can be found in the available information, but narcotics likely have relatively little effect on CBF and CMR in the normal, unstimulated nervous system. When changes do occur, the general pattern is one of modest reductions in both CBF and CMR. The inconsistencies in the literature may largely arise because the control states entailed paralysis and nominal sedation in many studies, often with N_2O alone. In these studies, in which substantial reductions in CBF and CMR were frequently observed, the effect of the narcotic was probably a combination of the inherent effect of the drug plus a substantial component attributable to reduction of arousal. Comparable effects related to reduction of arousal may occur and can be clinically important. However, they should be viewed as nonspecific effects of sedation or pain control, or both, rather than specific properties of narcotics. The following discussion emphasizes investigations in which control measurements were unlikely to have been significantly influenced by arousal phenomena.

Morphine. When morphine (~1 mg/kg) was administered as the sole drug to humans, no effect on global CBF and a 41% decrease in the $CMRO_2$ were observed. The latter is a substantial reduction, and the absence of a simultaneous adjustment in CBF is surprising. No other investigations of morphine have been conducted in humans alone. Administration of morphine (1 mg/kg and 3 mg/kg) with 70% N_2O to patients did not significantly change CBF or CMR.[48] The N_2O that was used might be expected to have caused a tendency toward increases in CBF. The relative absence of *net* changes in these variables from awake control measurements suggests a small-to-moderate depressive effect of morphine on CBF and CMR at this large dose. However, morphine can cause a substantial release of histamine in individual patients. Histamine is a cerebral vasodilator that will cause an increase in CBV and a CBF effect that will vary, depending on the systemic blood pressure response.

Autoregulation was observed to be intact between MAP values of 60 and 120 mm Hg in human volunteers anesthetized with a combination of morphine, 2 mg/kg, and 70% N_2O.[97]

Fentanyl. Fentanyl, in a dose range of 12 to 30 (mean, 16) μg/kg, in combination with 50% N_2O, reduced CBF and CMR modestly, by 21% and 26%, respectively, in comparison to the awake control state. The data for fentanyl-N_2O presented in Fig. 11.10 are derived from these patients. In combination with 0.4 mg/kg of diazepam, high dose fentanyl (100 μg/kg) led to a reduction of CBF by 25%, although part of this effect may well have been a result of benzodiazepine (see later discussion in the section, "Benzodiazepine") rather than fentanyl *per se*. In sedative doses of 1.5 μg/kg, fentanyl increased CBF in the frontal, temporal, and cerebellar areas simultaneous with decreases in discrete areas associated with pain-related processing. CO_2 responsiveness and autoregulation are unaffected, and the hyperemic CBF response to hypoxia remains intact.

In conclusion, fentanyl will cause a moderate global reduction in CBF and CMR in the normal quiescent brain and will, similar to morphine, cause larger reductions when administered during arousal.

Alfentanil. Administration of alfentanil, 320 μg/kg, to pentobarbital-anesthetized dogs[98] did not affect CBF, CMR, CO_2 responsiveness, autoregulation, or CBF response to hypoxia. No studies of the effects of alfentanil on the CMR in humans have been conducted. In patients in whom anesthesia was induced with thiopental, administration of 25 to 50 μg/kg of alfentanil transiently decreased MCAfv, indicating a slight reduction in CBF.[99] By contrast,[100] no change in MCAfv was observed in response to 25 to 50 μg/kg of alfentanil given to patients during the maintenance of anesthesia with isoflurane-N_2O. An evaluation of the surgical field in patients undergoing craniotomy to whom alfentanil was administered did not reveal any adverse events.[101,102]

In general, alfentanil does not significantly impact the cerebral circulation, provided that alfentanil induced reduction in MAP is prevented.

Sufentanil. Studies in humans indicate that sufentanil causes, depending on the dose, either no change or a modest reduction in CBF and CMR. Induction of anesthesia with 10 μg/kg of sufentanil[68] resulted in a 29% reduction in CBF and a 22% reduction in $CMRO_2$. In healthy human volunteers, 0.5 μg/kg of sufentanil[103] does not affect CBF.

Sufentanil, at doses of 1.0 and 2.0 μg/kg, decreases MCAfv in head injured patients with increased ICP.

A logical conclusion is that no change and no reduction in ICP occur as a result of the administration of either sufentanil or alfentanil. However, in some investigations in humans, sufentanil was associated with modest increases in ICP. The increases in ICP associated with sufentanil are likely the consequence, in part, of a normal autoregulatory response to the sudden reduction in MAP that can occur as a consequence of sufentanil administration.[104] Therefore sufentanil and fentanyl should be administered in a manner that does not produce a sudden reduction of MAP. Such a decrease will reduce CPP and may increase ICP, each of which, in sufficient extreme, may be deleterious. However, ICP increases attributed to sufentanil are small. Furthermore, conditions in the surgical field, including pressure under brain retractors[101] and the state of brain relaxation, revealed no adverse influences attributable to sufentanil. Accordingly, sufentanil need not be viewed as contraindicated in any way, although its effect on MAP should be followed closely.

Remifentanil. Investigations of moderate doses of remifentanil in patients have revealed effects similar to those of other synthetic narcotics (with the exception of its substantially shorter duration of action). In patients undergoing craniotomy for supratentorial space-occupying lesions, 1 μg/kg of remifentanil caused no change in ICP.[105] In a second investigation in patients undergoing craniotomies, approximately 0.35 μg/kg/min of remifentanil resulted in CBF values comparable to those observed with moderately deep anesthesia with either isoflurane-N_2O or fentanyl-N_2O,[106] and CO_2 responsiveness was preserved. Greater doses of remifentanil may have more substantial effects. MCAfv decreased by 30% in response to 5 μg/kg, followed by 3 μg/kg/min of remifentanil at a constant MAP in patients being anesthetized for bypass surgery.[69] However, a lower dose of 2 μg/kg, followed by an infusion of 3 μg/kg/min, did not affect MCAfV. Quantitatively, the effects of remifentanil appear to be similar to those of sufentanil.

Remifentanil was administered with other drugs that might influence cerebral hemodynamics. More recent studies in human volunteers have demonstrated that the infusion of small (sedative) doses of remifentanil can increase CBF. A PET study in human subjects to whom remifentanil, 0.05 and 0.15 μg/kg/min, was administered revealed increases in CBF in the prefrontal, inferior parietal, and supplementary motor cortices; reductions in CBF were observed in the cerebellum, superior temporal lobe, and midbrain gray matter.[105] The relative increase in CBF was greater with the administration of the larger dose of remifentanil. Similar data were obtained by Lorenz and colleagues,[107] who used magnetic resonance imaging (MRI) to determine CBF.[107] In a PET investigation in human volunteers,[108] remifentanil-induced increases in regional CBF within the limbic system were observed. Although the underlying mechanisms of the increases in CBF are not clear, disinhibition produced by the small-dose remifentanil infusion, or perhaps the sensation of side effects (e.g., warmth, comfort, pruritus),[107] may have contributed. When combined with N_2O, CBF and CO_2 reactivity is similar in patients given remifentanil or fentanyl.[106] In conclusion, sedative doses of remifentanil alone can cause minor increases in CBF. With larger doses or with the concomitant administration of anesthetic adjuvants, CBF is either unaltered or modestly reduced.

Benzodiazepines

Benzodiazepines cause parallel reductions in CBF and CMR in humans. CBF and $CMRO_2$ decreased by 25% when 15 mg of diazepam was given to patients with head injuries. The effects of midazolam on CBF (but not on CMR) have also been studied in humans. Administration of 0.15 mg/kg of midazolam to awake healthy human volunteers resulted in a 30% to 34% reduction in CBF.[71,109] In an investigation using PET scanning, a similar dose of midazolam led to a global 12% reduction in CBF; the decreases occurred preferentially in the brain regions associated with arousal, attention, and memory.[110] CO_2 responsiveness was preserved.[111]

The available data indicate that benzodiazepines cause a moderate reduction in CBF in humans, which is coupled to metabolism. The extent of the maximal reductions of CBF and CMR produced by benzodiazepines is probably intermediate between the decreases caused by narcotics (modest) and barbiturates (substantial). It appears that benzodiazepines should be safe to administer to patients with intracranial hypertension, provided that respiratory depression (and an associated increase in $Pa{CO_2}$) or hypotension do not occur.

Flumazenil is a highly specific, competitive benzodiazepine receptor antagonist. It had no effect on CBF when administered to nonanesthetized human volunteers.[109,112] However, flumazenil reverses the CBF-, CMR-, and ICP-lowering effects of midazolam. When patients were aroused from midazolam anesthesia with flumazenil at the conclusion of craniotomy for brain tumor resection,[113] no change in either CBF or CMR was observed. By contrast, severe increases in ICP occurred when flumazenil was given to patients with severe head injury in whom ICP was not well controlled.[114] These latter observations are consistent with animal investigations during which flumazenil not only reversed the CBF and CMR effects of midazolam, but it also caused a substantial, although short-lived, overshoot above premidazolam levels in both CBF and ICP by 44% to 56% and 180% to 217%, respectively. The CMR did not rise above control levels, thus indicating that the increase in CBF was not metabolically coupled. The CBF overshoot effect is unexplained, but it may be a neurogenically mediated arousal phenomenon. Flumazenil should be used cautiously to reverse benzodiazepine sedation in patients with impaired intracranial compliance.

Droperidol

No human investigations of the CBF and CMR effects of droperidol have been conducted in isolation. However, the information available from animal investigations and combination drug administration in humans,[115] taken together, suggests that droperidol is not a cerebral vasodilator and probably has little effect on CBF and CMR in humans. The occasional increases in ICP that have been observed[115] probably reflect normal autoregulation-mediated vasodilation in response to an abrupt decrease in MAP.

Ketamine

Among the intravenous anesthetics, ketamine is unique in its ability to cause increases in both CBF and CMR.[116] Animal studies indicate that the changes in the CMR are regionally variable; substantial increases occur in limbic system structures with modest changes or small decreases in cortical structures.[117] PET studies in humans have demonstrated that subanesthetic doses of ketamine (0.2-0.3 mg/kg) can increase global CMR by approximately 25%.[118] The greatest increase in the CMR occurred in the frontal and anterior cingulate cortex. A relative reduction in the CMR in the cerebellum was also observed. Commercially available formulations of ketamine contain both the *(S)*- and *(R)*-ketamine enantiomers. The *(S)*-ketamine enantiomer substantially increases CMR, whereas the *(R)* enantiomer tends to decrease the CMR, particularly in the temporomedial cortex and in the cerebellum.[119] These changes in the CMR are accompanied by corresponding changes in CBF.[120] Global, as well as regional, increases in CBF in humans that were not accompanied by similar increases in the $CMRO_2$ after the administration of *(S)*-ketamine enantiomer have been observed. Both subanesthetic and anesthetic doses of ketamine increased global CBF by approximately 14% and 36%, respectively, without altering global $CMRO_2$. As expected, in the face of an unchanged CMR and increased CBF, the oxygen extraction ratio was reduced.[77] The majority of investigations indicate that autoregulation is maintained during ketamine anesthesia,[121] and CO_2 responsiveness is preserved. A recent metaanalysis concluded that, in humans, ketamine administration increases CBF, particularly in the anterior cingulate gyrus, medial prefrontal cortex, and occipital lobes. In aggregate, the available data indicate that ketamine does increase CBF, and the accompanying increase in CMR is at best modest. Ketamine does not increase CBV.[122]

The anticipated increase in ICP with an increase in CBF has not been confirmed to occur in humans. When examined in their entirety, the available data indicate that ketamine does not increase ICP in patients with nontraumatic neurologic illness[122] nor in patients with traumatic brain injury.[122] In fact, decreases in ICP occur when relatively large anesthetic doses of ketamine (1.5-5 mg/kg) are administered to patients with head injuries who are sedated with propofol.[123] However, it should be noted that, in most of the studies in which the ICP effects of ketamine have been evaluated, patients received sedative agents in addition to ketamine. It has been established that anesthetic drugs (diazepam, midazolam, isoflurane-N_2O, propofol, opioids, methohexital) blunt or eliminate the increases in ICP or CBF associated with ketamine.[116,124,125] Accordingly, although ketamine is probably best avoided as the sole anesthetic drug in patients with impaired intracranial compliance, it may be cautiously given to patients who are simultaneously receiving adjunctive sedative drugs.

Lidocaine

In nonanesthetized human volunteers, reductions in CBF and CMR of 24% and 20%, respectively, were observed after the administration of 5 mg/kg of lidocaine over a 30-minute period, followed by an infusion of 45 μg/kg/min.[126] When very large doses (160 mg/kg) were given to dogs maintained on cardiopulmonary bypass, the reduction in the $CMRO_2$ was apparently more than that observed with large-dose barbiturates.[127] The membrane-stabilizing effect of lidocaine probably reduces the energy required for the maintenance of membrane integrity.

The effectiveness of bolus doses of thiopental, 3 mg/kg, and lidocaine, 1.5 mg/kg, in controlling the acute increase in ICP that occurred after the application of a pin head holder or skin incision in patients undergoing craniotomies has been assessed.[128] The two regimens were equally effective in causing a reduction in ICP. However, the decrease in the MAP was greater with thiopental. Accordingly, a bolus dose of lidocaine is a reasonable adjunct to the prevention or treatment of acute increases in ICP and can prevent increases in ICP associated with endotracheal suctioning. Although large doses of lidocaine can produce seizures in humans, lidocaine-induced seizures have not been reported in anesthetized humans. Nonetheless, lidocaine doses should be adjusted to achieve serum levels less than the seizure threshold (>5-10 μg/mL) in awake humans. After a 2-mg/kg bolus, peak serum concentrations of 6.6 to 8.5 μg/mL are below the seizure threshold. Bolus doses of 1.5 to 2.0 mg/kg therefore seem appropriate.

INHALED ANESTHETICS

Volatile Anesthetics

The pattern of volatile anesthetic effects on cerebral physiology is quite different than that of intravenous anesthetics, which generally cause parallel reductions in CMR and CBF. All volatile anesthetics, in a manner similar to intravenous sedative-hypnotic drugs, suppress cerebral metabolism in a dose-related fashion.[129-132] Volatile anesthetics also possess intrinsic cerebral vasodilatory activity as a result of direct effects on vascular smooth muscle. The net effect of volatile anesthetics on CBF is therefore a balance between a reduction in CBF caused by CMR suppression and an augmentation of CBF caused by the direct cerebral vasodilation. When administered at a dose of 0.5 MAC, CMR suppression–induced reduction in CBF predominates, and net CBF decreases in comparison with the awake state. At 1 MAC, concentrations of isoflurane, sevoflurane, or desflurane, CBF remains unchanged; at this concentration, CMR suppression and vasodilatory effects are in balance. Beyond 1 MAC, the vasodilatory activity predominates, and CBF significantly increases, even though the CMR is substantially reduced (Fig. 11.11).[133] Vasodilation with increasing doses of volatile agents lead to an attenuation of cerebral autoregulation. With large doses, autoregulation is abolished and cerebral perfusion becomes pressure passive (Fig. 11.12).

The increase in CBF produced by volatile anesthetics at doses larger than 1 MAC has been referred to as reflecting a loss of neurovascular coupling. However, coupling (CBF adjustments paralleling changes in the CMR) persists during anesthesia with volatile anesthetics.[134-138] Accordingly, the conclusion should be that the CBF/CMR ratio is altered (increased) by volatile anesthetics. This alteration is dose related, and under steady-state conditions, increasing doses of volatile agents lead to greater CBF/$CMRO_2$ ratios[130,139]—that is, higher MAC levels cause greater luxury perfusion.

The important clinical consequences of the administration of volatile anesthetics are derived from the increases in

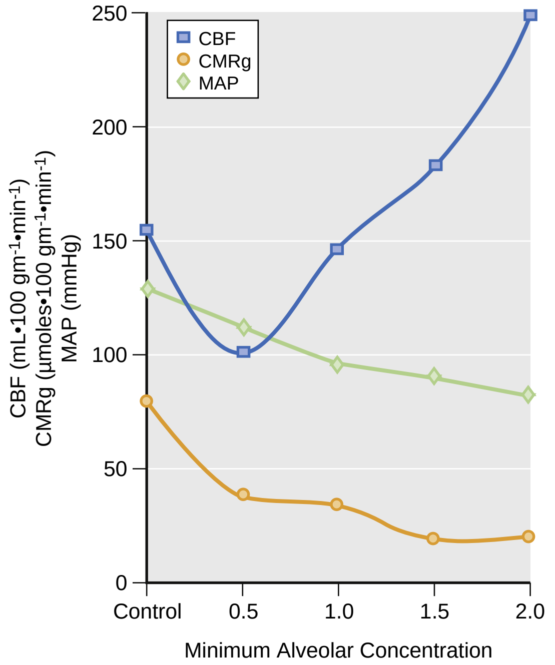

Fig. 11.11 Relationship between changes in the cerebral metabolic rate of glucose *(CMRg)* and cerebral blood flow *(CBF)* in the motor-sensory cortex in rats during isoflurane anesthesia. The majority of the suppression in the CMR caused by isoflurane has occurred by 1 minimum alveolar concentration; CBF is not increased in this concentration range. Thereafter, additional isoflurane causes little further reduction in the CMR, and cerebral vasodilation occurs. These data (± standard deviation) from Maekawa and colleagues[133] suggest the importance of metabolic coupling in determining the effects of isoflurane on CBF. *MAP,* Mean arterial pressure.

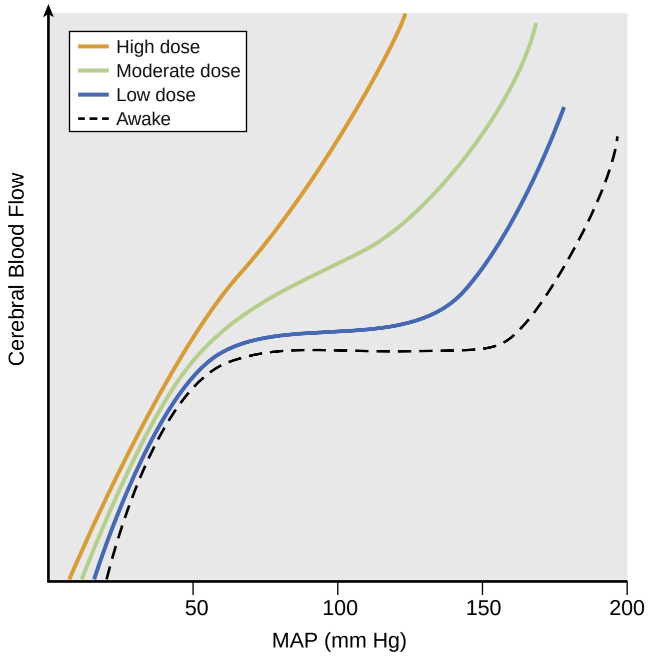

Fig. 11.12 Schematic representation of the effect of increasing concentrations of a typical volatile anesthetic drug on autoregulation of cerebral blood flow. Dose-dependent cerebral vasodilation results in attenuation of autoregulatory response to increasing mean arterial pressure *(MAP)*. Both the upper and lower thresholds are shifted to the left.

CBF and CBV—and consequently ICP—that can occur. Of the commonly used volatile anesthetics, the order of vasodilating potency is approximately halothane ≫ enflurane > desflurane ≈ isoflurane > sevoflurane.

Effects on cerebral blood flow. Volatile anesthetics possess intrinsic vasodilatory activity, and they not only modify cerebral autoregulation, but they also produce a dose-dependent decrease in arterial blood pressure. Hence, their effects on CBF and CMR are best evaluated when arterial blood pressure is maintained at a constant level. In addition, the cerebrovascular effects of volatile anesthetics are modulated by the simultaneous administration of other CNS-active drugs. The control state—awake, sedated, or anesthetized—against which the CBF and CMR effects of volatile anesthetics are compared, is important to recognize. The best information concerning the cerebrovascular effects of volatile anesthetics is obtained in studies during which a nonanesthetized (awake) control state is used.

Data on the cerebrovascular effects of halothane and enflurane are limited. Initial studies in humans demonstrated that the administration of 1 MAC halothane significantly increases CBF, even when systemic blood pressure is substantially reduced, in comparison with preanesthetic CBF. When the MAP is maintained at 80 mm Hg, 1.1 MAC levels of halothane increase CBF by as much as 191% and decrease the CMR by approximately 10% (Fig. 11.13).[140,141] When compared with awake values, 1.2 MAC enflurane also increased CBF and decreased CMR by 45% and 15%, respectively.[142] The dramatic increases in CBF with a simultaneous modest reduction in the CMR attest to the cerebral vasodilatory properties of halothane and enflurane. Isoflurane, by contrast, does not increase CBF as much as halothane or enflurane. At concentrations of 1.1 MAC, isoflurane increases CBF by approximately 19% when arterial blood pressure is maintained within the normal range. The CMR is reduced by approximately 45%.[137]

Both sevoflurane and desflurane can reduce CBF significantly in humans when compared with CBF in awake, nonanesthetized patients. At 1 MAC concentrations, sevoflurane[143] and desflurane[142] decreased CBF by 38% and 22% and CMR by 39% and 35%, respectively. These results, which suggest that the cerebral vasodilation produced by isoflurane is greater than that produced by sevoflurane and desflurane, were obtained with CBF measured by the Kety-Schmidt technique. This technique primarily measures CBF within the cortex and therefore may have substantially underestimated global CBF. PET studies in healthy humans have shown that sevoflurane dose-dependently suppresses the $CMRO_2$ and CBF; at 1 MAC levels, the reduction in CBF and $CMRO_2$ is approximately 50% and 50% to 60%, respectively.[83,84] Even with a significant reduction in CBF, the administration of sevoflurane does not cause a decrease in CBV. Other investigations in humans, most using the measurement of MCAfv by transcranial Doppler, indicate that differences in the effects of isoflurane, desflurane (Fig. 11.14*A*), and sevoflurane are modest.[144-147] Unfortunately, a strictly quantitative comparison among these volatile anesthetics is not possible because of the variations in arterial blood pressure among study group patients. In addition, some discrepancy exists among studies in the literature regarding the magnitude of the effects of volatile anesthetics on CBF. Much of this inconsistency may occur as a result of the interaction of regionally selective CBF methods with the heterogeneity within the cerebrum of the CBF effects of volatile anesthetics. (See the later section, "Distribution of Changes in Cerebral Blood Flow/Cerebral Metabolic Rate.")

The anesthetic properties of xenon were recognized several decades ago, but this anesthetic is only now being evaluated for possible use in patients. The MAC of xenon has been estimated to be 63% to 71%, with female patients having significantly lower MAC values (51%).[147] Xenon exerts its anesthetic effect via noncompetitive antagonism of the *N*-methyl-D-aspartate receptor (NMDAR),[148] although activation of the TREK two-pore K^+ channel may also play a role.[149] In healthy humans, the administration of 1 MAC xenon resulted in a reduction in CBF by approximately 15% in the cortex and by 35% in the cerebellum. Interestingly, CBF in white matter increased by 22%.[150] This reduction in CBF is accompanied by a parallel reduction of the cerebral metabolic rate of glucose (CMRg) by 26%.[151] Cerebral autoregulation and CO_2 reactivity are preserved during xenon anesthesia in animals.[152] Under background pentobarbital anesthesia in an experimental model of increased ICP, the administration of xenon did not increase ICP, and the response to both hypocapnia and hypercapnia was preserved.[153] Diffusion of xenon into air-containing spaces such as the bowel does occur, although the magnitude of air expansion is considerably less than that with N_2O.[154] Nonetheless, caution will have to be exercised with the use of xenon in patients with intracranial air. These data indicate that xenon has a favorable profile for neuroanesthesia.

Effects on cerebral metabolic rate. All volatile anesthetics cause reductions in CMR. The degree of reduction in $CMRO_2$ that occurs at a given MAC is less with halothane

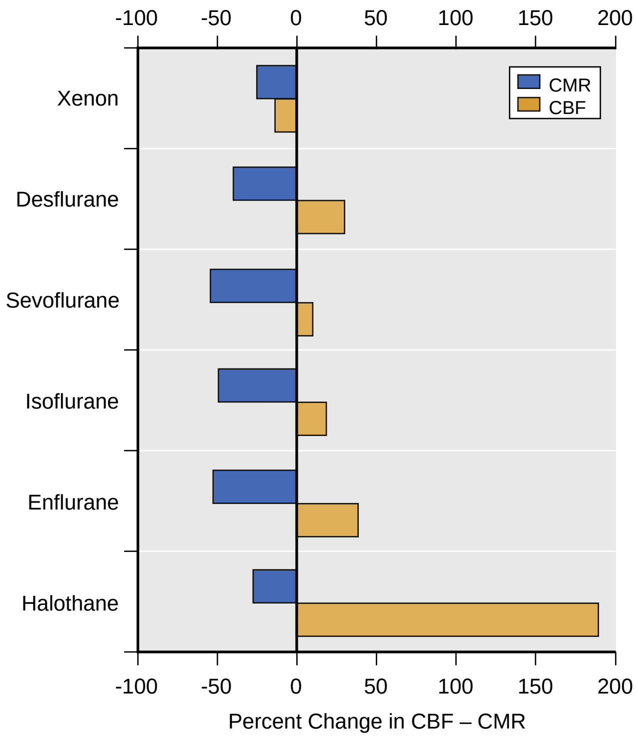

Fig. 11.13 Estimated changes in cerebral blood flow *(CBF)* and the cerebral metabolic rate of oxygen ($CMRO_2$) caused by volatile anesthetics. The CBF data for halothane, enflurane, and isoflurane were obtained during anesthesia (with blood pressure support) at 1.1 minimum alveolar concentration (MAC) in humans[356] and are expressed as percent change from awake control values. The $CMRO_2$ data for halothane, enflurane, and isoflurane were obtained in cats[130,140] and are expressed as percent change from N_2O-sedated control values. The data for sevoflurane were obtained during 1.1 MAC anesthesia in rabbits and are expressed as percent change from a morphine-N_2O–anesthetized control state.[132] CBF values were obtained in patients who received 1 MAC sevoflurane anesthesia.[143] Desflurane data were obtained in patients to whom 1 MAC desflurane was administered.[141] *CMR*, Cerebral metabolic rate.

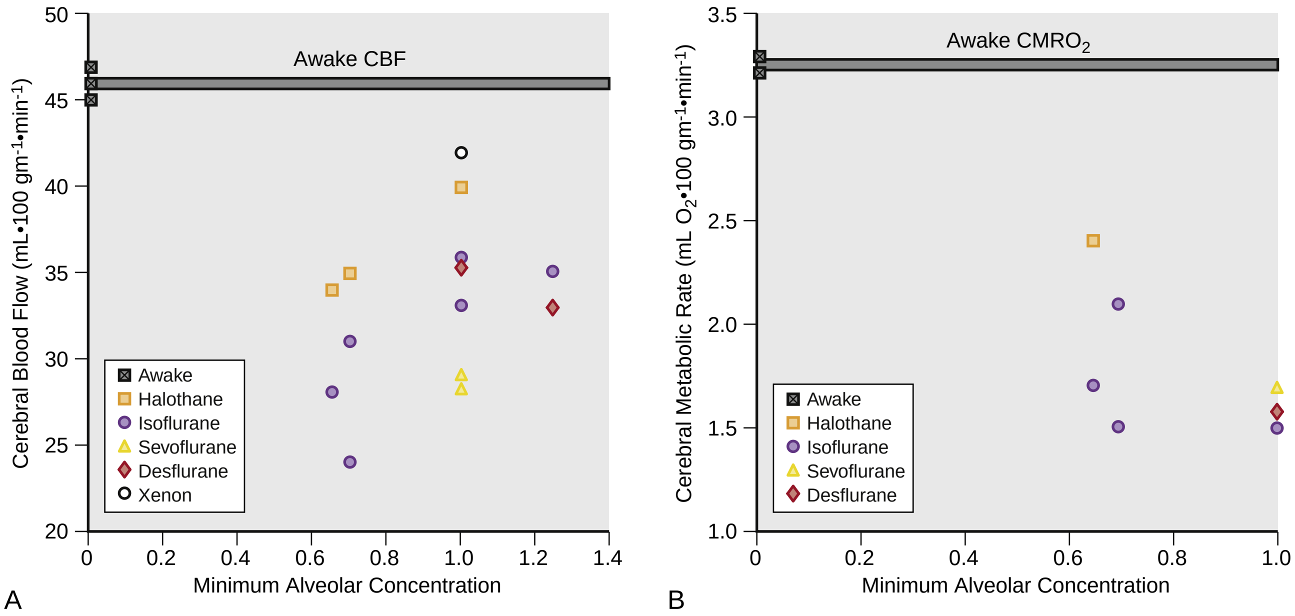

Fig. 11.14 Effect of volatile anesthetics on cerebral blood flow *(CBF)* (A) and the cerebral metabolic rate of oxygen *($CMRO_2$)* (B) in awake humans. The results are a composite of CBF and $CMRO_2$ values obtained from a number of separate investigations.[72,130,131,135-137,139-146,356-358] In these studies, arterial partial pressure of carbon dioxide ($PaCO_2$) was maintained in the normocapnic range (~35-40 mm Hg), and mean arterial pressure was supported. In most of the investigations, CBF was measured by a radioactive xenon washout technique; this technique primarily measures cortical CBF and, as such, may underestimate global CBF. This, in addition to species differences, probably account for the disparities between the data on the CBF effects attributed to volatile agents in this figure and Fig. 11.13.

than with the other four anesthetics. Sevoflurane's effect on the CMRO$_2$ is very similar to that of isoflurane. The available information, derived in separate investigations, suggests that desflurane causes slightly less suppression of the CMRO$_2$ than isoflurane, especially at concentrations above 1 MAC.[131] Although a direct comparison of the CMRO$_2$ effects of all of the volatile anesthetics has not been performed in humans, doses of 1 MAC isoflurane, sevoflurane, and desflurane clearly reduce the CMRO$_2$ by 25%,[155] 38%,[141] and 22%,[156] respectively. In PET studies, halothane (0.9 MAC) and isoflurane (0.5 MAC) can decrease the CMRg by 40% and 46%, respectively.[85,157] The decrease in the CMRO$_2$ is dose-related. With isoflurane (and almost certainly desflurane and sevoflurane as well), the maximal reduction is simultaneously attained with the occurrence of EEG suppression,[131] which occurs at clinically relevant concentrations, in the range of 1.5 to 2 MAC in humans. With additional isoflurane, 6% end-tidal concentration results in no further reduction in the CMR and no indication of metabolic toxicity. Halothane presents a contrast to this pattern. Halothane concentrations more than 4 MAC are required to achieve EEG suppression in animals, and additional halothane causes a further reduction in the CMRO$_2$ in concert with alterations in energy charge. The latter changes, which are reversible, suggest interference with oxidative phosphorylation by halothane.

Some nonlinearity exists in the CBF and CMR dose-response relationships for volatile anesthetics. The initial appearance of an EEG pattern associated with the onset of anesthesia with halothane, enflurane, and isoflurane is accompanied by a sharp decline in the CMRO$_2$.[131] Thereafter, the CMRO$_2$ declines in a slower dose-dependent manner. Such an effect has also been demonstrated for sevoflurane. In a dose escalation study in humans, the greatest reduction in entropy (i.e., a measure of anesthetic depth) was observed with 1 MAC sevoflurane anesthesia, with lesser reductions occurring at increasing concentrations.[158]

Distribution of changes in cerebral blood flow and cerebral metabolic rate. The regional distribution of anesthetic-induced changes in CBF and CMR differs significantly between halothane and isoflurane. Halothane produces relatively homogeneous changes throughout the brain. CBF is globally increased, and CMR is globally depressed. The changes caused by isoflurane are more heterogeneous. Increases in CBF are greater in subcortical areas and hindbrain structures than in the neocortex.[136,159] The converse is true for the CMR, with a larger reduction in the neocortex than in the subcortex.[133] In humans, 1 MAC sevoflurane (Fig. 11.15) results in a reduction in CBF within the cortex and the cerebellum. With an increase in sevoflurane dose, CBF within the cortex decreases further. By contrast, flow increases in the cerebellum with doses greater than 1.5 MAC.[83] These effects of sevoflurane are similar to those produced by isoflurane.[83,159] Desflurane has not been evaluated by local CBF studies. However, considering the similarity of its effects on the EEG (suggesting similar cortical CMR and CBF effects), an assumption of similar heterogeneity in CBF distribution seems reasonable, pending further investigation. These distribution differences may explain certain apparent contradictions in reported CBF effects in the existing literature for isoflurane. Methods that assess global hemodynamic effects reveal greater changes than those that emphasize the cortical compartment. For instance, when a xenon surface washout technique is employed (measurement of local cortical flow only), no increase in CBF occurred when isoflurane was administered to patients undergoing craniotomy.[160]

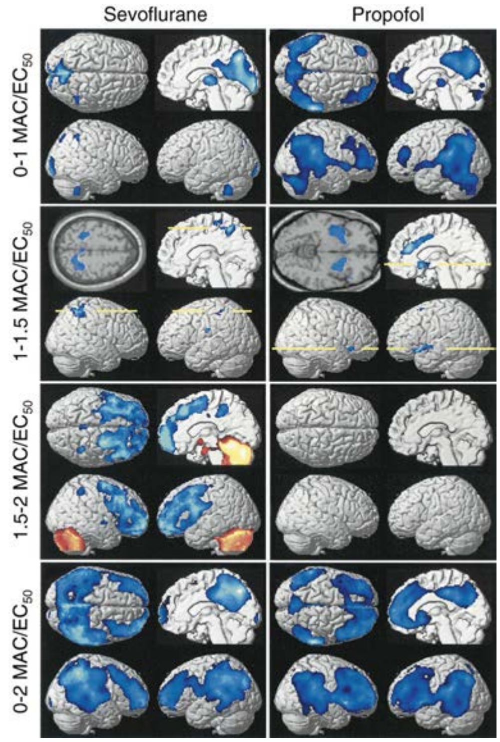

Fig. 11.15 Dose-dependent redistribution of cerebral blood flow (CBF) in humans. Positron-emission tomography (PET) scans demonstrate a dose-dependent reduction in CBF in both sevoflurane-anesthetized *(left)* and propofol-anesthetized *(right)* subjects. During sevoflurane anesthesia, there is a concentration dependent reduction in CBF within the cerebrum (indicated by blue color). An increase in concentration from 1.5 to 2 minimum alveolar concentration *(MAC)* leads to an increase in CBF within the cerebellum (indicated by the yellow-red color). A gradual reduction in the mean arterial pressure (MAP) occurred with increasing concentrations of sevoflurane, and the MAP was not supported. The CBF values would be expected to be considerably greater had blood pressure been maintained within the normal range. Therefore the CBF values represented in this figure probably *underestimate* true CBF during sevoflurane anesthesia. Propofol was administered in EC$_{50}$ equivalents, defined as the plasma concentration that prevented movement in response to a surgical stimulus in 50% of patients. The target plasma propofol concentrations were 0, 6, 9, and 12 μg/mL. In propofol-anesthetized subjects, CBF was uniformly decreased and redistribution of CBF was not observed. (Modified from Kaisti K, Metsähonkala L, Teräs M, et al. Effects of surgical levels of propofol and sevoflurane anesthesia on cerebral blood flow in healthy subjects studied with positron emission tomography. *Anesthesiology*. 2002;96:1358–1370.)

Time dependence of cerebral blood flow effects. The effects of volatile anesthetics on CBF are time-dependent in animal investigations. After an initial increase, CBF decreases and reaches a steady state near pre–volatile agent levels between 2.5 and 5 hours after exposure.[161-163] The mechanism of this effect is not

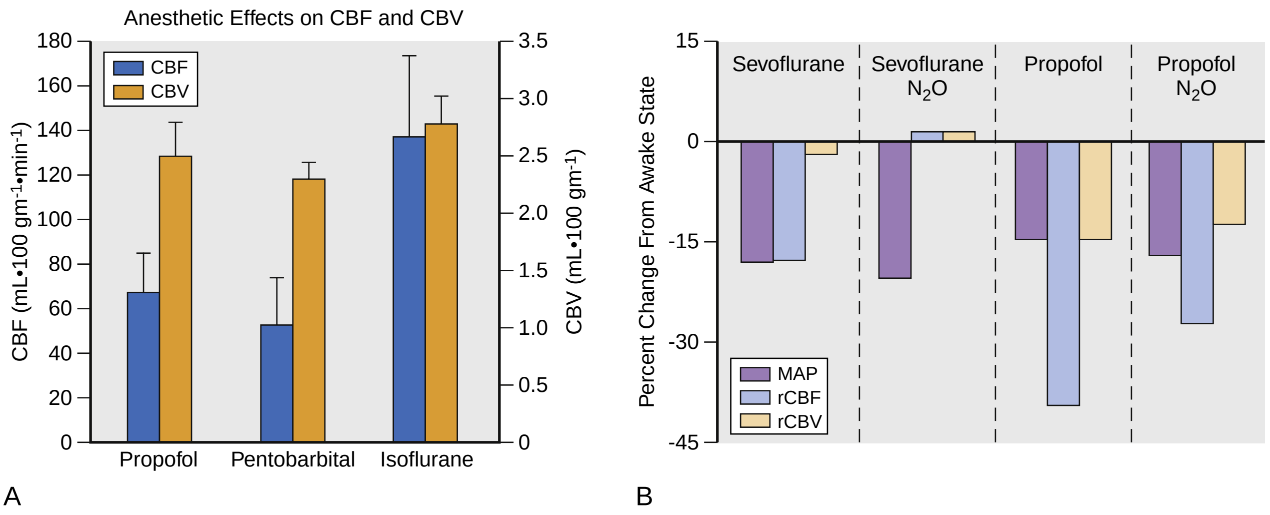

Fig. 11.16 Effect of anesthetic drugs on cerebral blood flow *(CBF)* and cerebral blood volume *(CBV)*. (A) When compared with isoflurane, propofol and pentobarbital effected substantial reductions in CBF. However, reductions in CBV were more modest.[151] (B) Although sevoflurane effected a significant reduction in regional CBF (rCBF), regional CBV (rCBV) was unchanged. Had blood pressure been supported to normal levels, rCBV may have been greater than the awake state. By contrast, propofol effected a significant reduction in both rCBF and rCBV. These data indicate that the magnitude of the effect of anesthetics on rCBF is substantially greater than on rCBV. Hence, decreases in rCBF may not lead to equivalent reductions in rCBV. *MAP,* Mean arterial pressure; *N_2O,* nitrous oxide.

understood, and the phenomenon was not evident in humans studied during a 3- or 6-hour exposure to halothane, isoflurane, desflurane, or sevoflurane.[146,164]

Cerebral blood volume. The extensive investigation of the influence of volatile anesthetics on CBF has been primarily based on the concern that the cerebral vasodilation produced by volatile anesthetics might increase ICP. However, it is CBV and not CBF, per se, that influences ICP. Most of the intracranial blood is within the cerebral venous circulation; although a reasonable correlation exists between vasodilation-induced increases in CBF and CBV, the magnitude of changes in CBF is considerably greater than that in CBV (see Fig. 11.9). Hence, changes in CBF do not reliably predict changes in CBV and, by extension, in ICP. CBV is considerably greater during isoflurane anesthesia than during propofol or pentobarbital anesthesia.[63] In human volunteers, 1 MAC sevoflurane reduced regional CBF but not regional CBV; by contrast, propofol reduced both regional CBF and regional CBV (Fig. 11.16).[84] In addition, CBV responds to changes in $PaCO_2$ by a reduction in CBV with hypocapnia and an increase in CBV with hypercapnia. The magnitude of the change in CBV is, however, less than the change in CBF. In aggregate, although the effect of anesthetics and interventions on CBF may parallel the effect on CBV, substantial qualitative and quantitative differences may well be observed.

Carbon dioxide responsiveness and autoregulation. CO_2 responsiveness is well maintained during anesthesia with all volatile anesthetics.[145,165,166] As with all vasodilators, CBF is preserved up to lower MAP values during the administration of volatile anesthetics with no evidence of differences among the various anesthetics. Direct comparisons of CBF with isoflurane, desflurane, and sevoflurane anesthesia during hypotension are not available. By contrast, autoregulation of CBF in response to increasing arterial blood pressure is impaired, which is most apparent with the anesthetics that cause the most cerebral vasodilation and are dose related. Sevoflurane may cause less impairment of the autoregulatory response to increasing blood pressure than other volatile anesthetics. Recent studies surprisingly report no change in MCAfv in response to phenylephrine-induced increases in the MAP during anesthesia with 1.2 to 1.5 MAC sevoflurane[167,168] or in CBF during hemorrhagic hypotension.[169] The autoregulatory response to increasing blood pressure may be pertinent during acute episodes of hypertension, such as during laryngoscopy or mismatch of surgical stimulation to anesthetic depth.

Cerebral vasodilation by anesthetics—clinical implications. Isoflurane, desflurane, and sevoflurane may have a modest cerebral vasodilating effect in the human cortex when administered at doses of 1 MAC or less. In fact, the administration of volatile anesthetics may produce a net decrease in CBF (see Fig. 11.14*A*). These data, however, should be interpreted with the knowledge that the critical variable of interest in the clinical setting is CBV. Although a direct correlation exists between CBF and CBV, as noted earlier, the relationship is not strictly 1:1. The magnitude of the changes in CBV is significantly less than the magnitude of the changes in CBF, and modest reductions in CBF may not necessarily be accompanied by reductions in CBV. This finding is exemplified by clinical investigations in which a significant increase in ICP (and by extension, CBV) was observed in patients to whom isoflurane was administered at doses that should reduce CBF.[170,171] Although induction of hypocapnia mitigated the increase in ICP, hyperventilation may not be effective in blunting isoflurane-induced increases in ICP in patients with intracranial tumors.[172] In experimental investigations of cerebral injury, volatile anesthetics significantly increased ICP, which was not ameliorated by hypocapnia.[173] Collectively, these data suggest that volatile anesthetics have modest effects on cerebral hemodynamics in patients with normal intracranial compliance. However, in patients with abnormal intracranial compliance, the potential for volatile anesthetic–induced increases in CBV and ICP exist. Accordingly, volatile anesthetics should be used with caution in the setting of large or rapidly expanding mass lesions, unstable ICP, or other significant cerebral physiologic derangements in which CO_2 responsiveness and neurovascular coupling may be impaired. When they occur (e.g., a somnolent, vomiting patient with papilledema; a large mass; compressed basal cisterns), the clinician may well be advised to use a predominantly intravenous technique until such time as the cranium and dura are open and the effect of the anesthetic technique can be directly evaluated. Such circumstances will be relatively uncommon in elective neurosurgery.

Situations in which the CMR has been decreased by drug administration or disease processes should also justify caution in the use of volatile anesthetics. As previously noted, the vasodilation mediated increase in CBF induced by a volatile anesthetic is in part, and at low doses, offset by an opposing metabolically mediated vasoconstriction (see Fig. 11.11). In situations in which the CMR is already reduced, the vasodilatory activity will predominate and, therefore, the increase in CBF will be greater. For example, when CMR is only slightly reduced by morphine, isoflurane does not cause significant increase in CBF. However, under thiopental anesthesia, the introduction of isoflurane significantly increases CBF.[135] Similarly, prior propofol anesthesia produces near maximal suppression of CMR; in this situation, introduction of any of the volatile agents leads to significant increases in CBF.[89] In essence, antecedent CMR suppression unmasks the vasodilatory action of volatile anesthetics. These data also suggest that caution must be exercised in the administration of volatile anesthetics in pathologic conditions, such as traumatic brain injury, in which metabolism is already reduced.

The net vasodilating effects of equi-MAC concentrations of isoflurane, desflurane, and sevoflurane are less in humans than that of halothane, and the former are probably therefore preferable if a volatile anesthetic is to be used in the setting of impaired intracranial compliance. When hypocapnia is established before the introduction of halothane, the increases in ICP that might otherwise occur in a normocapnic patient with poor intracranial compliance can be prevented or greatly attenuated. Nonetheless, isoflurane, desflurane, or sevoflurane are preferred because the margin for error is probably wider than with halothane.

Nitrous Oxide

N_2O can cause increases in CBF, CMR, and ICP. At least a portion of the increases in CBF and CMR may be the result of a sympathoadrenal-stimulating effect of N_2O. The magnitude of the effect considerably varies according to the presence or absence of other anesthetic drugs (Fig. 11.17).[174,175] When N_2O is administered alone, substantial increases in CBF and ICP can occur. In sharp contrast, when N_2O is administered in combination with intravenous drugs, including barbiturates, benzodiazepines, narcotics, and propofol, its cerebral-vasodilating effect is attenuated or even completely inhibited. The addition of N_2O to anesthesia established with a volatile anesthetic will result in moderate increases in CBF.

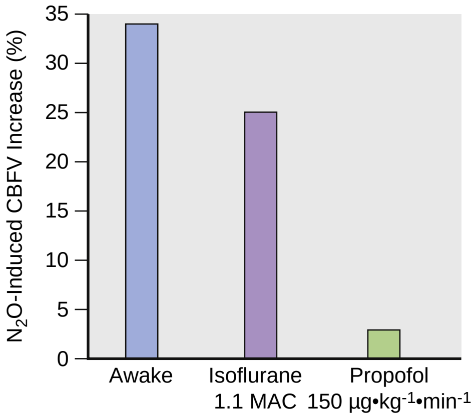

Fig. 11.17 Mean percent increases in cerebral blood flow velocity *(CBFV)* in the middle cerebral artery of normocapnic subjects exposed to 60% nitrous oxide (N_2O) after control recording in three conditions: awake;[174] 1.1 minimum alveolar concentration (MAC) of isoflurane;[179] and propofol, 150 µg/kg/min.[175]

The most dramatic increases in ICP or CBF in humans and experimental animals have occurred when N_2O was administered alone or with minimal background anesthesia. For instance, before and during spontaneous breathing of 66% N_2O by patients with intracranial tumors, mean ICP increased from 13 to 40 mm Hg.[176] The increases in CBF observed in humans are more modest than those observed in animals but are still substantial.[174] Whether these substantial increases represent the effects of N_2O, per se, or whether they reflect the nonspecific effects of a *second-stage* arousal phenomenon is not known.

When N_2O is administered in conjunction with certain intravenous anesthetics, its CBF effect may be considerably attenuated. In an investigation of patients with intracranial tumors and poor intracranial compliance (mean preinduction ICP, 27 mm Hg),[177] 50% N_2O introduced during barbiturate anesthesia and after the induction of hypocapnia had a negligible effect on ICP. Benzodiazepines administered alone have been shown to blunt the CBF response to N_2O in both animals and humans.[107] Narcotics appear to have a similar effect. Anesthesia with 1 mg/kg morphine and 70% N_2O resulted in no change in CBF from awake control values.[66] Because of the very minor effect of morphine on CBF, these data suggest that N_2O did not cause substantial cerebral vasodilation. Although the addition of N_2O to propofol anesthesia in children increased MCAfv in one study,[178] similar increases were not demonstrated by other investigators.[175]

In most investigations, including several in humans, during which N_2O has been added to a volatile anesthetic of 1 MAC or greater, substantial increases in CBF have been recorded.[179,180] A comparison of an approximately equi-MAC substitution of N_2O for isoflurane revealed that CBF was greater by 43% with 0.75 MAC isoflurane and 65% N_2O in comparison to 1.5 MAC isoflurane.[181] Several investigations have confirmed that CBF will be less with 1 MAC isoflurane than with a 1 MAC combination achieved with 50% to 65% N_2O and isoflurane.[179,181,182] These observations are consistent with a substantial additive vasodilating effect of N_2O in the presence of a volatile agent.

This vasodilating effect of N_2O may be positively correlated with the concentration of inhaled drug[180] and suggests that, in general, the increase in CBF caused by N_2O is exaggerated at higher concentrations of both halothane and isoflurane. Of importance, however, is the observation that the administration of 50% N_2O to healthy volunteers did not significantly alter CBV.[183] In support of this observation, N_2O did not have any effect on CBV when added to a background of 1 MAC sevoflurane anesthesia.[84] Although N_2O can increase CBF, these data indicate that its effect on CBV is modest.

Effects of nitrous oxide on cerebral metabolic rate. No uniform agreement has been reached concerning the effect of N_2O on the CMR. Parallel changes in CBF and CMR, increases in CBF without alteration of the CMR, and CMR alteration occurring without changes in CBF have all been reported. These findings are, doubtless, the product of differences in species, methods, depth of background anesthesia, and interactions with simultaneously administered anesthetics. In a recent investigation in humans, the administration of 70% N_2O on a background of either sevoflurane or propofol anesthesia resulted in modest increases in the $CMRO_2$, thus indicating that N_2O does indeed increase cerebral metabolism.[84]

The CBF response to CO_2 is preserved during the administration of N_2O.[184]

Clinical implications. Despite the inconsistencies that are evident, the vasodilatory action of N_2O can be clinically significant in neurosurgical patients with reduced intracranial compliance. However, N_2O-induced cerebral vasodilation can be considerably blunted by the simultaneous administration of intravenous anesthetics. By contrast, the addition of N_2O to a volatile drug–based anesthetic can modestly increase cerebral metabolism and blood flow. N_2O has been widely used in neurosurgery, and banishing it is inconsistent with the accumulated experience. Nonetheless, in circumstances wherein ICP is persistently elevated or the surgical field is persistently *tight*, N_2O should be viewed as a potential contributing factor. Because N_2O rapidly enters a closed gas space, it should be avoided or omitted when a closed intracranial gas space may exist or intravascular air is a concern.

MUSCLE RELAXANTS

Nondepolarizing Relaxants

The only recognized effect of nondepolarizing muscle relaxants on the cerebral vasculature occurs via the release of histamine. Histamine can result in a reduction in CPP because of the simultaneous increase in ICP (caused by cerebral vasodilation) and a decrease in the MAP. It is not entirely clear whether histamine directly causes cerebral vasodilation or whether it is a secondary (autoregulatory) response to a reduction in the MAP. *d*-Tubocurarine is the most potent histamine releaser among available muscle relaxants. Metocurine, atracurium, and mivacurium also release histamine in lesser quantities. This effect is likely to be clinically inconsequential unless these muscle relaxants are administered in the large doses necessary to achieve endotracheal intubation conditions rapidly. Of this group of drugs, cisatracurium has the least histamine-releasing effect. No evidence of histamine release was observed after the administration of 0.15 mg/kg of cisatracurium to neurosurgical patients in the intensive care unit.[185] Yet, cisatracurium's slow onset of action makes it less useful for a rapid sequence induction of anesthesia.

Vecuronium, in relatively large doses, does not have a significant effect on cerebral physiology in patients with brain tumors. The other aminosteroids, pipecuronium and rocuronium, should be similarly without direct effect, and no adverse events have been reported.

The indirect actions of relaxants may also have effects on cerebral physiology. Muscle relaxation may reduce ICP because coughing and straining are prevented, which decrease central venous pressure with a concomitant reduction in cerebral venous outflow impedance.

A metabolite of atracurium, laudanosine, may be epileptogenic. However, although large doses of atracurium caused an EEG arousal pattern in dogs, CBF, CMR, and ICP were unaltered.[186] In rabbits, the administration of laudanosine did not increase the severity of the epileptoid activity caused by the direct application of a cephalosporin to the cortical surface.[187] It appears highly unlikely that epileptogenesis will occur in humans with modest atracurium administration.[188]

In summary, vecuronium, pipecuronium, rocuronium, atracurium, mivacurium, cisatracurium, metocurine, and pancuronium (if acute MAP increases are prevented with the latter) are all reasonable muscle relaxants for use in patients with or at risk for intracranial hypertension. Doses of metocurine, atracurium, and mivacurium should be limited to ranges not associated with hypotension.

Rocuronium is increasingly being used for the induction of anesthesia, as well as for intraoperative relaxation. It has the most rapid onset time of any nondepolarizing muscle relaxant. With sugammadex, even a profound neuromuscular blockade can be rapidly reversed (see Chapters 27 and 28). The cerebrovascular effects of sugammadex have not yet been evaluated.

Succinylcholine

Succinylcholine can produce modest increases (~5 mm Hg) in ICP in lightly anesthetized humans. This effect appears to be the result of cerebral activation (as evidenced by EEG changes and increases in CBF) caused by afferent activity from the muscle spindle apparatus.[189] As might be expected with what appears to be an arousal phenomenon, deep anesthesia prevents succinylcholine-induced increases in ICP. The increase in ICP is also blocked by paralysis with vecuronium and by defasciculation with metocurine, 0.03 mg/kg.[190] The efficacy of other defasciculating anesthetics has not been examined in humans.

Although succinylcholine *can* produce increases in ICP, it can still be used for a rapid sequence induction of anesthesia. No change in ICP was observed after the administration of succinylcholine, 1 mg/kg, to 10 nonparalyzed, ventilated neurosurgical patients in the intensive care unit, 6 of whom had sustained a head injury.[191] Their observations are relevant because it is in precisely this population of patients that the issue of the use of succinylcholine arises most frequently. Considering that the ICP effects of succinylcholine may be an arousal phenomenon caused by increased afferent traffic from muscle spindles,[189] it is reasonable to assume that disease processes that substantially blunt the level of consciousness might similarly blunt this response. As with many anesthetics, the concern should

TABLE 11.3 Effects of Anesthetic Agents on the Rate of Cerebrospinal Fluid Secretion and Absorption

	Halothane	Enflurane	Isoflurane	Desflurane	Fentanyl	Etomidate
Secretion	↓	↑	—	↑	—	↓
Absorption	↓	↓	↑	—	↑	↑

Upward arrows indicate an increase in the rate of cerebrospinal fluid absorption or secretion, and downward arrows indicate a decrease. The information is presented nonquantitatively, and effects may vary with dose.

not be whether it is used but how it is used. When contraindications do not exist, with proper attention to the control of CO_2 tension, arterial blood pressure, and depth of anesthesia and after defasciculation, little hazard should attend succinylcholine administration.

Other Effects of Anesthetics on Cerebral Physiology

CEREBROSPINAL FLUID DYNAMICS

Anesthetics have been shown to influence both the rate of formation and the rate of reabsorption of CSF. Table 11.3 provides nonquantitative information about the direction of the influences of common anesthetic drugs. All the information has been derived from animals,[192-198] and these processes have not been examined in humans. Of the volatile anesthetics, halothane decreases the secretion of CSF, isoflurane has no effect, and enflurane and desflurane increase secretion. Absorption of CSF is reduced by halothane and enflurane, unchanged by desflurane, and increased by isoflurane. A theoretic concern might be in the setting of a prolonged closed-cranium procedure in a patient with poor intracranial compliance. The most deleterious potential combination of effects in a patient with poor intracranial compliance is increased CSF production and decreased reabsorption. This pattern occurs with enflurane in the dog, which is perhaps another reason (in addition to the potential for epileptogenesis in the presence of cerebral injury and hypocapnia) for omission of enflurane in this circumstance.

BLOOD-BRAIN BARRIER

In the majority of the body's capillary beds, fenestrations between endothelial cells are approximately 65 Å in diameter. In the brain, with the exception of the choroid plexus, in the pituitary, and in the area postrema, tight junctions reduce this pore size to approximately 8 Å. As a result, large molecules and most ions are prevented from entering the brain's interstitium (BBB). A limited number of studies of anesthetic effects on the BBB have been conducted. In experimental animals, 1% isoflurane leads to extravasation of albumin into the thalamus, indicating some compromise of the BBB integrity. At higher doses, isoflurane (3%) significantly increases protein extravasation, not only in the thalamus but also in the cortex.[199] This disruption of the BBB is quantitatively similar to that achieved by mannitol. In experimental models of brain injury, isoflurane has been reported to both exacerbate[200] and ameliorate[201] edema formation in the injured brain. Whether these effects are the result of isoflurane action at the BBB, *per se*, or to hemodynamic perturbations attendant upon anesthesia is not known. The clinical relevance of the potential BBB modulation by anesthetics is not clear. To the authors' knowledge, no peer-reviewed investigation has attempted a comparison of anesthetic effects on BBB function during anesthesia in normotensive humans.

EPILEPTOGENESIS

An extensive review of the pro- and anticonvulsant effects of anesthetics and adjuvants is available.[202,203] Several commonly used anesthetics have some epileptogenic potential, particularly in predisposed individuals. A concern is that seizure activity may go unrecognized in an anesthetized and paralyzed patient and may result in neuronal injury if substrate demand (CMR) exceeds supply for a prolonged period.[204] A second concern is that the epileptogenic effect will persist in the postanesthesia period when seizures may occur in less well-controlled circumstances than those that exist in the surgical unit. In practice, it appears that spontaneous seizures during or after anesthesia have been extremely rare events. Nonetheless, in patients with processes that might predispose them to seizures, the use of potentially epileptogenic drugs should be avoided in situations during which reasonable alternatives are available.

Volatile Anesthetics

Enflurane is potentially epileptogenic in clinical setting. Of particular relevance to neuroanesthesia is the observation that hypocapnia potentiates seizure-type discharges during enflurane anesthesia. A 50% decrease in the $CMRO_2$ was noted in human volunteers anesthetized with 3% enflurane; however, with the onset of seizure activity, the $CMRO_2$ returned to normal,[205] thus indicating preservation of neurovascular coupling. No evidence suggests that this type of EEG activity is deleterious when oxygen delivery is maintained during the event. However, because seizure activity can elevate brain metabolism by as much as 400%, the use of enflurane, especially at high doses and with hypocapnia, should probably be avoided in patients predisposed to seizures.

The EEG-activating property of enflurane has been used intraoperatively to activate and identify seizure foci that are to be surgically resected, and in this situation, spike activity not preoperatively present has been observed to persist after surgery.[206] However, adverse outcomes related to enflurane-induced seizures have not been reported.

Isoflurane can cause EEG spiking and myoclonus, but it has not been associated, in the experimental setting, with the frank epileptoid activity induced by enflurane. The clinical experience with isoflurane is extremely large, and unexplained seizure-like activity has been reported in only two patients. One occurrence was intraoperative,[207] and the other was immediately postoperative.[208] Therefore epileptogenesis does not appear to be a clinical concern with isoflurane. In fact, isoflurane has been successfully used to control EEG seizure activity in refractory status epilepticus.[209]

Seizures occur during the induction of anesthesia with high concentrations of sevoflurane in children, including those without a recognized seizure diathesis.[210] In two healthy humans, EEG burst suppression with 2 MAC sevoflurane was accompanied by epileptiform discharges that were observed during EEG monitoring.[211] These discharges were associated with a significant increase in CBF, thus demonstrating that neurovascular coupling was preserved. In patients with temporal lobe epilepsy, the administration of 1.5 MAC sevoflurane elicited widespread paroxysmal EEG activity. Of note was the observation that the paroxysmal activity was not restricted to the ictal focus and that the administration of sevoflurane did not provide any assistance in localizing the epileptogenic region of the brain.[212] The development of tonic-clonic movements suggestive of seizure activity has also been reported in otherwise healthy patients on emergence from sevoflurane anesthesia.[213,214] In all of the reported cases of seizure activity attributable to sevoflurane anesthesia, untoward sequelae have not been documented. These reports highlight sevoflurane's ability, albeit small, to evoke epileptiform activity; accordingly, the use of sevoflurane in patients with epilepsy should be undertaken with appropriate caution.

Methohexital

Myoclonic activity is sometimes observed with methohexital. Accordingly, this anesthetic has been used to activate seizure foci during cortical mapping.[211] In neurosurgical patients to whom larger doses of methohexital were administered to produce burst suppression of the EEG, refractory seizures have occurred.[215] Consequently, it appears that patients with seizures of temporal lobe origin, typically of the psychomotor variety or those to whom large doses are administered, are at risk for seizure activation by methohexital. However, prolonged seizure activity after single-dose methohexital administration has not been reported in patients who undergo ECT.

Ketamine

Ketamine can elicit seizures in patients with an epileptic diathesis.[216] Depth electrode recordings in epileptic patients have revealed the occurrence of isolated subcortical seizure activity originating in the limbic and thalamic areas during ketamine anesthesia and demonstrated that this subcortical activation may not be reflected in surface EEG recordings. On only two occasions, seizures have also been reported after ketamine anesthesia in subjects who were neurologically normal;[217,218] seizure thresholds may have been lowered by aminophylline in one of these instances. However, ketamine has also been employed for the purpose of controlling status epilepticus. Therefore, ketamine-induced seizure activity is not of significant concern.

Etomidate

Etomidate frequently produces myoclonus that is not associated with epileptiform activity on the EEG.[219] A single instance of severe, sustained myoclonus immediately after anesthesia with etomidate by infusion has been reported.[220] Etomidate has also been shown to precipitate generalized epileptic EEG activity in epileptic patients,[221] and its use in this population should probably be avoided. However, it has been electively used in low doses to activate seizure foci for the purposes of intraoperative EEG localization.[222] In the experience of the authors (unpublished), selective activation of a quiescent focus can be achieved with 0.1 mg/kg etomidate. Larger doses are more likely to lead to generalized activation.

Etomidate is also associated with longer seizures in response to ECT than seizures that occur after the administration of methohexital or propofol. Remarkably, etomidate, in the dose range of 0.15 to 0.3 mg/kg, does not cause dose-related seizure inhibition during ECT, as is readily demonstrated with methohexital or propofol.

The preceding information notwithstanding, no convincing reports indicate epileptogenesis in subjects who are neurologically normal, and the use of etomidate need not be restricted on this basis. In fact, etomidate has been used to control refractory status epilepticus.

Propofol

Abnormal body movements and opisthotonos can occur after propofol anesthesia. However, systematic studies in humans,[223] although identifying the occurrence of occasional dystonic and choreiform movements, have failed to confirm propofol as a proconvulsant. Furthermore, ECT seizures were shorter after induction with propofol than after induction with methohexital,[224] which is more consistent with an *anticonvulsant* effect. In addition, propofol sedation has been widely used during *awake* resection of seizure foci and other intracranial lesions. Although pronounced high-amplitude beta-frequency activity in the EEG has been observed,[225] unexpected incidences of seizures have not been reported.

Narcotics

Seizures or limbic system hypermetabolism (or both) can be readily elicited in some animal species with narcotics. Although an increase in CBF in deep brain structures associated with pain processing has been observed in human volunteers,[226] humans do not have a clinically apparent correlate of the hypermetabolism effect observed in animals. Several anecdotal accounts, unaccompanied by EEG recordings, have reported the occurrence of grand mal convulsions in patients who received both high and low doses of fentanyl. However, systematic investigations of EEG changes during the administration of relatively large doses of fentanyl, sufentanil, and alfentanil in humans have *not* documented neuroexcitatory activity,[227] and the seizures may have been an exaggerated rigidity phenomenon. There are exceptions. Partial complex seizures on the induction of anesthesia with fentanyl in patients undergoing anterior temporal lobectomy have been reported.[228] Eight of the nine patients displayed electrical seizure activity at a range of clinically relevant fentanyl doses (mean, 26 μg/kg).[228] Another study found that alfentanil, 50 μg/kg, augmented temporal lobe spike activity in patients with temporal lobe epilepsy.[229] Untreated rigidity may, itself, also have important CNS consequences. ICP elevation can occur during narcotic-induced rigidity, probably as a consequence of cerebral venous congestion.

NEONATAL ANESTHETIC NEUROTOXICITY

This subject is discussed in detail in Chapter 78.

Cerebral Physiology in Pathologic States

CEREBRAL ISCHEMIA—PATHOPHYSIOLOGIC CONSIDERATIONS

Critical Cerebral Blood Flow Thresholds

The brain has a high rate of energy utilization and very limited energy storage capacity. The brain is therefore extremely vulnerable in the event of interruption of substrate (e.g., oxygen, glucose) supply. Under normal circumstances, global CBF is maintained at approximately 50 mL/100 g/min. In the face of a declining CBF and therefore oxygen supply, neuronal function deteriorates in a progressive manner rather than in an all-or-none fashion (Fig. 11.18). There is substantial reserve below normal CBF levels, and not until EEG evidence of ischemia begins to appear is CBF decreased to approximately 20 mL/100 g/min. At a CBF level of approximately 15 mL/100 g/min, the cortical EEG is isoelectric. However, only when CBF is reduced to approximately 6 to 10 mL/100 g/min are indications of potentially irreversible membrane failure, such as increased extracellular potassium[230] and a loss of the direct cortical response, rapidly evident. As CBF decreases in the flow range between 15 and 10 mL/100 g/min, a progressive deterioration in energy supply occurs and eventually leads to membrane failure and neuronal death at a time course that may last hours rather than minutes. The brain regions falling within this CBF range (6-15 mL/100 g/min) encompass brain tissue in which neuronal dysfunction is temporarily reversible but within which neuronal death will occur if flow is not restored; such regions are referred to as the *ischemic penumbra*.[230,231] Studies defining progression to cerebral infarction within the penumbra have been performed principally in the cerebral cortex of primates, and the actual CBF levels at which the various decrements in function occur may vary with both anesthetic[232] and species. However, in humans anesthetized with halothane and N_2O, the CBF threshold for the initial EEG change[233] is similar to that observed in the animal investigations.

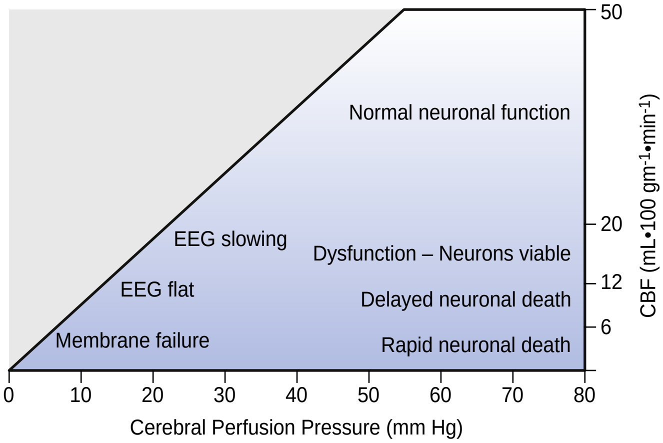

Fig. 11.18 Relationships between cerebral perfusion, cerebral blood flow *(CBF)*, the electroencephalogram *(EEG)*, and the functional status and viability of neurons. Note that in the approximate CBF range of 6 to 12 mL/100 g/min, the energy supply is insufficient to support electrophysiologic activity (i.e., flat EEG) but can prevent complete membrane failure and neuronal death for extended periods. These areas are referred to as the *ischemic penumbra*.[230] The data are derived from studies on the cerebral cortex of barbiturate-anesthetized baboons[230,359] and nonanesthetized monkeys.[360] The CBF and mean arterial pressure thresholds may vary with anesthetic and species.[232]

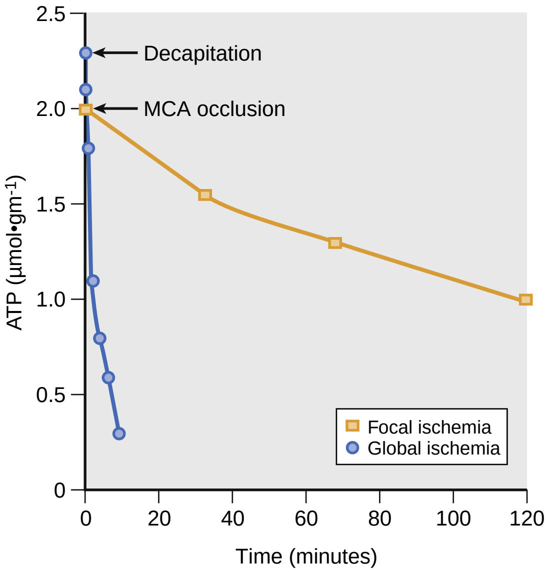

Fig. 11.19 Comparison of rates of failure of energy supply (adenosine triphosphate *[ATP]*) in complete global ischemia in dogs (produced by decapitation[235]) and in incomplete focal ischemia in monkeys (middle cerebral artery *[MCA]* occlusion[234]). In the presence of residual cerebral blood flow *(CBF)*, energy supply failure is substantially delayed.

Models of Cerebral Ischemia

How different is complete cerebral ischemia, as occurs during cardiac arrest, and incomplete cerebral ischemia, as may occur during occlusion of a major cerebral vessel or severe hypotension? From the clinician's vantage, the important difference is that the residual (i.e., collateral) blood flow during incomplete ischemia may result in enough delivery of oxygen to allow some generation of ATP and thereby stave off the catastrophic irreversible membrane failure that occurs within minutes during normothermic complete cerebral ischemia.[234] This difference in the rate of failure of the energy supply (Fig. 11.19)[234,235] can result in significantly greater apparent tolerance for focal or incomplete ischemia than for complete global ischemia (e.g., cardiac arrest).

Energy Failure and Excitotoxicity

Energy failure is the central event that occurs during cerebral ischemia.[236] ATP is required for the maintenance of the normal membrane ionic gradient, and energy failure is rapidly attended by membrane depolarization and influx of sodium (Na^+) and calcium (Ca^{2+}) into the neuron. Voltage-dependent Ca^{2+} channels are then activated, and Ca^{2+} gains entry into the cytosol. Depolarization of presynaptic terminals also results in the release of massive quantities of excitatory neurotransmitters, particularly glutamate, into the synaptic cleft. Activation of glutamatergic receptors, the NMDAR, and the α-amino-3-hydroxy-5-methyl-4-isoxazopropionic acid receptors (AMPARs), adds to the influx of Na^+ and Ca^{2+} (Fig. 11.20). Initiation of cellular signaling by the activation of the mGluR leads to the release of stored Ca^{2+} from the endoplasmic reticulum (ER) via

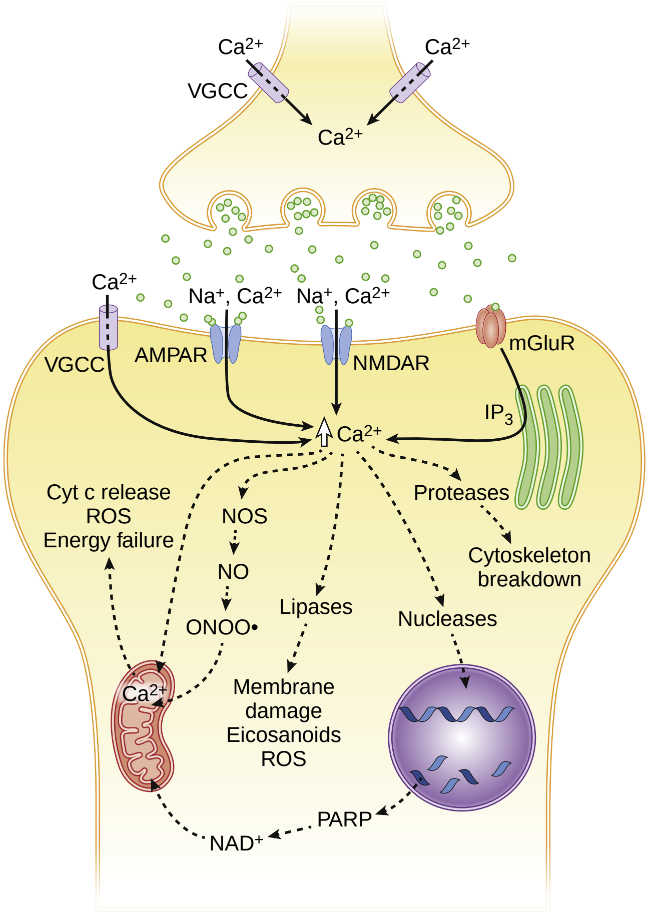

Fig. 11.20 During ischemia, depletion of adenosine triphosphate (ATP) leads to neuronal depolarization and the subsequent release of supranormal quantities of neurotransmitters, especially glutamate. Excessive stimulation of ligand-gated channels and the simultaneous opening of voltage-dependent calcium *(Ca^{2+})* channels permit rapid entry of Ca^{2+} into neurons. Stimulation of metabotropic glutamate receptors (mGluRs) generates inositol 1,4,5-triphosphate *(IP_3)*, which causes the release of Ca^{2+} from the endoplasmic reticulum (ER) and mitochondria. Activation of the α-amino-3-hydroxy-5-methyl-4-isoxazopropionic acid receptors *(AMPAR)*–gated subset of glutamate receptors also permits excessive entry of sodium *(Na^+)*. Excessive free Ca^{2+} results in the activation of numerous enzymes: protease activation causes the breakdown of the cytoskeleton of the neuron; lipases damage plasma membrane lipids and release arachidonic acid (AA), which is metabolized by cyclooxygenases and lipoxygenases to yield free radicals and other mediators of cell injury; activation of nitric oxide synthase *(NOS)* leads to the release of nitric oxide *(NO)* and, in turn, the generation of peroxynitrite *(ONOO)*, a highly reactive free radical; and activated endonucleases damage DNA, thereby rendering the neuron susceptible to apoptosis. Injury to the mitochondria leads to energy failure, generation of free radicals, and the release of cytochrome *c* (*cyt c*) from the mitochondria; the latter is one of the means by which neuronal apoptosis is initiated. *mGluR,* Metabotropic glutamate receptor; *NAD^+,* oxidized form of nicotinamide adenine dinucleotide; *NMDAR, N*-methyl-D-aspartate receptor; *PARP,* poly-ADP-ribose polymerase; *ROS,* reactive oxygen species; *VGCC,* voltage-gated calcium channel.

inositol 1,4,5-triphosphate (IP_3) receptors. Ionic influx is accompanied by an influx of water, and neuronal swelling rapidly occurs after membrane depolarization. The injury that is initiated by excessive glutamatergic activity is referred to as *excitotoxicity*.

Ca^{2+} is a ubiquitous second messenger in cells and is a cofactor required for the activation of a number of enzyme systems. The rapid, uncontrolled increase in cytosolic Ca^{2+} levels initiates the activation of a number of cellular processes that contribute to injury. Cytoskeletal proteins such as actin are cleaved by activated proteases. These enzymes also degrade a number of the protein constituents of the neuron. Lipases attack cellular lipids and produce membrane damage. An important lipase, phospholipase A_2, releases fatty acids such as AA from membranes. Metabolism of AA to prostaglandins and leukotrienes by cyclooxygenase and lipoxygenase is accompanied by the generation of superoxide free radicals. The latter, in combination with other free radicals generated in response to mitochondrial injury, can lead to lipid peroxidation and membrane injury. Prostaglandins and leukotrienes also evoke an inflammatory response and are powerful chemotactic drugs. Activation of platelets within cerebral microvessels, as well as an influx of white blood cells into damaged areas, aggravate the ischemic injury by occluding the vasculature.

Deoxyribonucleic acid (DNA) damage is also an important event during ischemic neuronal injury. Generation of free radicals from AA metabolism, from injured mitochondria, and from the production of peroxynitrite from NO leads to oxidative injury to DNA. Activation of endonucleases also produces DNA strand breaks. Under normal circumstances, DNA injury results in the activation of poly–adenosine diphosphate [ADP]–ribose polymerase (PARP), an enzyme that participates in DNA repair. With excessive DNA injury, PARP activity dramatically increases, which can lead to the depletion of nicotinamide adenine dinucleotide (NAD^+), a substrate of PARP. NAD^+ is also an important coenzyme in energy metabolism, and its depletion further exacerbates energy failure.

Lactate formation is an additional element of the pathophysiologic process. Lactic acid is formed as a result of the anaerobic glycolysis that takes place after failure of the supply of oxygen. The associated decrease in pH contributes to the deterioration of the intracellular environment. An increased preischemic serum glucose level may accelerate this process by providing additional substrate for anaerobic glycolysis.

NO, which has emerged as a probable mediator of CBF changes in many normal physiologic states (see the section “Cerebral Metabolic Rate”), is also of relevance to pathophysiologic ischemia. NO is, in fact, a weak free radical that in turn leads to the generation of a more reactive species (peroxynitrite), and it is the *killer substance* used by macrophages. In cerebral ischemia, NO is probably both friend and foe. During a period of focal ischemia, the vasodilating effect of NO (probably constitutively elaborated NO of endothelial origin) probably serves to augment collateral CBF. However, in the postischemic phase, NO (probably derived from neurons or macrophages) contributes to neuronal injury.

Collectively, the simultaneous and unregulated activation of a number of cellular pathways overwhelms the reparative and restorative processes within the neuron and ultimately leads to neuronal death.

The Nature of Neuronal Death

The neuronal death that occurs in response to these processes has been categorized as necrotic or apoptotic in nature. Necrotic death mediated by excitotoxic injury, is characterized by rapid cellular swelling, condensation and pyknosis of the nucleus, and swelling of the mitochondria and ER. A characteristic of these necrotic neurons is the presence of acidophilic cytoplasm.[237] Necrotic neuronal death results in local infiltration of the brain by inflammatory cells. A considerable amount of collateral damage is a consequence of this inflammation.

Neuronal apoptosis, a form of *cellular suicide*, has also been demonstrated in a variety of models of cerebral ischemia. Apoptosis is characterized by chromatin condensation, involution of the cell membrane, swelling of mitochondria, and cellular shrinkage. In the later stages of apoptosis, neurons fragment into several apoptotic bodies, which are then cleared from the brain.[237] The lack of a substantial inflammatory response to apoptotic death limits injury to surrounding neurons that have survived the initial ischemic insult.

A number of biochemical pathways that lead to apoptosis have been described. Initiation of apoptosis by the release of cytochrome *c* from injured mitochondria has been studied extensively (Fig. 11.21). Cytochrome *c* is restricted from the cytoplasm by the outer mitochondrial membrane.[238] When mitochondria are injured, pores within the outer membrane allow cytochrome *c* to be released into the cytoplasm, where it interacts with procaspase-9 and apoptosis-activating factor (APAF) to produce an apoptosome. Procaspase-9 undergoes activation by proteolytic cleavage. Activated caspase-9 then activates caspase-3. The latter serves as an executor of apoptosis by cleaving a number of protein substrates that are essential in DNA repair (such as PARP). Activation of caspase-3 can also occur by inflammatory signaling via tumor necrosis factor alpha (TNF-α) and the activation of caspase-8.[239] It should be noted that the neuronal injury that occurs in response to ischemia cannot be easily divided into necrosis or apoptosis. The nature of neuronal death probably encompasses a spectrum in which some neurons undergo either necrosis or apoptosis, whereas others undergo cell death that has features of both necrosis and apoptosis.

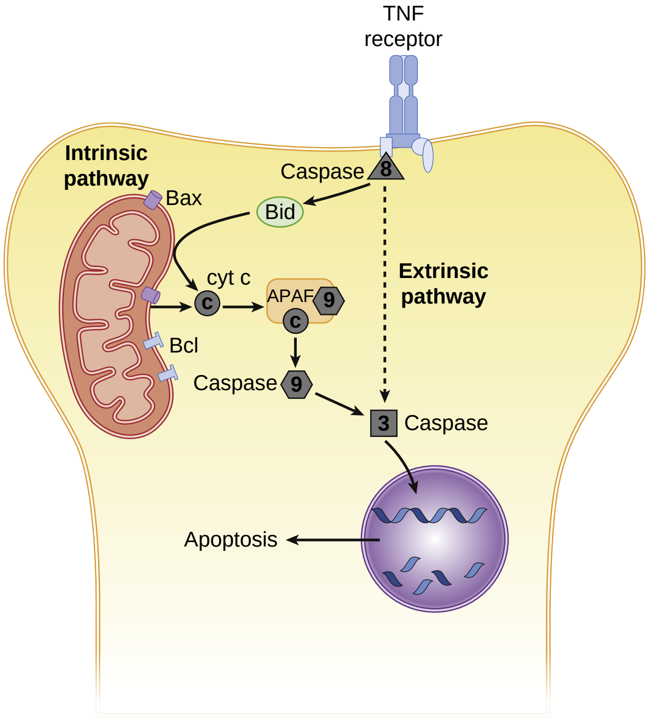

Fig. 11.21 Cellular processes that lead to neuronal apoptosis. Cytochrome *c (cyt c)*, which is normally restricted to the space between the inner and outer mitochondrial membranes, is released in response to mitochondrial injury. Cyt c, in combination with apoptosis-activating factor *(APAF)*, activates caspase-9 by proteolytic cleavage. Activated caspase-9 then leads to the activation of caspase-3. This enzyme cleaves a number of substrates, including those necessary for DNA repair. Within the mitochondria, Bax augments and Bcl prevents the release of cyt c. The release of cyt c can also be initiated by Bid, a substance that is activated by caspase-8 via tumor necrosis factor *(TNF)* signaling. In addition, caspase-8 can directly activate caspase-3. Excessive activation of poly-ADP-ribose polymerase, an enzyme integral to DNA repair, depletes cellular stores of oxidized nicotinamide adenine dinucleotide (NAD^+). Depletion of NAD^+ further exacerbates the energy failure because of its critical role in energy metabolism.

Timing of Neuronal Death

The traditional concept of ischemic injury was that neuronal death was restricted to the time of ischemia and during the early reperfusion period. However, more recent data indicate that postischemic neuronal injury is a dynamic process during which neurons continue to die for a long period after the initiating ischemic insult (Fig. 11.22).[240] This delayed neuronal death, which was first demonstrated in models of global cerebral ischemia, has been demonstrated during focal ischemia as well. The extent of delayed neuronal death depends on the severity of the ischemic insult. With severe ischemia, most neurons undergo rapid death. With more moderate insults, neurons that survive the initial insult undergo delayed death. This ongoing neuronal loss contributes to the gradual expansion of cerebral infarction after focal ischemia. In experimental studies, evidence of cerebral inflammation, which can theoretically contribute to further injury, has been demonstrated even 6 to 8 months after the primary ischemia.

The occurrence of delayed neuronal death has important implications for the evaluation of studies in which neuroprotective strategies are being investigated. A wide variety of interventions have shown neuroprotective efficacy in studies in which the extent of injury is evaluated within 3 to 4 days after ischemia. However, this neuroprotective efficacy may not be sustained. Recent data indicate that cerebral infarction undergoes gradual expansion and that a reduction in injury attributed to a particular therapeutic intervention is no longer apparent when the injury is evaluated after a long postischemic recovery period.[240] Long-term (>1 month) evaluation of the efficacy of a particular intervention is therefore important.

Much of the literature on the pathophysiologic process of cerebral ischemia has primarily been focused on neuronal injury. However, recent work has highlighted the importance of the contribution of astrocytes, microglia, vascular cells (e.g., endothelium, smooth muscle cells, pericytes), basement membranes, and extracellular matrix to stroke. These individual components in aggregate form the neurovascular unit. A detailed understanding of the contribution of each component of the neurovascular unit is a prerequisite, not only for the protection of the brain against ischemic and traumatic injury, but also for therapeutic approaches for the regeneration of the CNS.

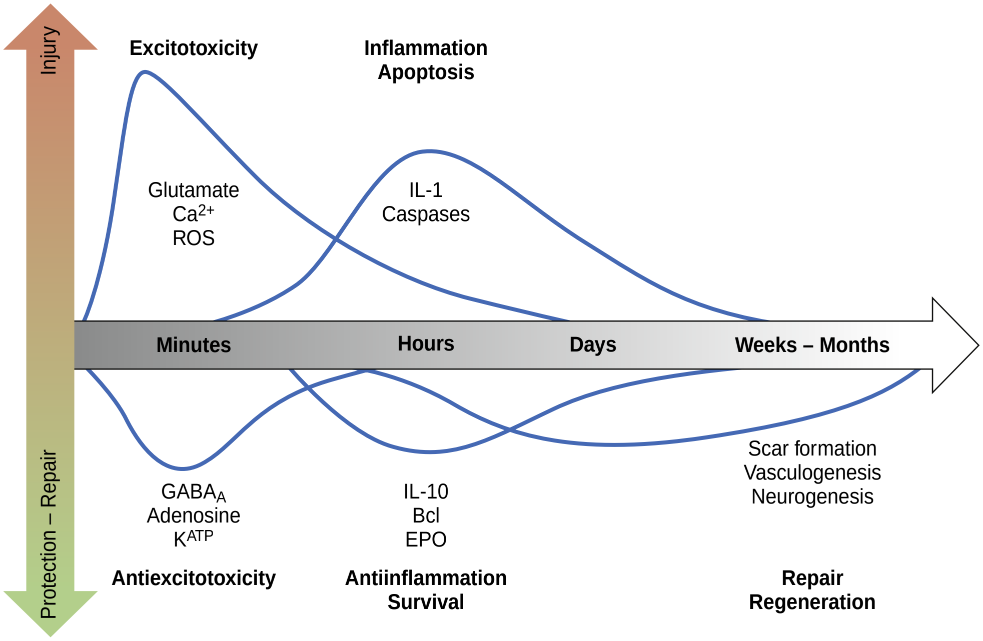

Fig. 11.22 Time course of neuronal death. Excitotoxic (glutamate-mediated) injury results in neuronal death within the first few hours after the onset of ischemia. Brain tissue injury elicits an inflammatory response—an important process in the removal of injured tissue and in healing—that leads to a substantial amount of collateral damage. Inflammation-mediated neuronal death can continue for several days. Neuronal apoptosis can occur in injured neurons that survived the initial insult. Apoptotic neuronal death has been demonstrated to occur for many days after the initiating ischemic insult. It is now apparent that ischemic neuronal death is a dynamic process during which neurons continue to die for a long period. *Ca^{2+},* Calcium; *EPO,* erythropoietin; *GABAA,* gamma-aminobutyric acid A; *K^{ATP}*, adenosine triphosphate–regulated potassium; *IL-1,* interleukin 1; *IL-10,* interleukin 10; *ROS,* reactive oxygen species. BRAIN PROTECTION

Despite intense investigative efforts, pharmacologic agents that can protect the brain against ischemic injury have not been identified. The mainstay in the reduction of brain injury in the setting of acute ischemic stroke is thrombolysis. Management of thrombolysis has been reviewed in guidelines for the early management of patients with acute ischemic stroke.[241] Intravenous alteplase is recommended for patients in whom the time from onset of symptoms to treatment is less than 3 hours. Contraindications to thrombolysis include inability to identify onset of symptoms, intracranial hemorrhage, previous stroke or head trauma within 3 months, recent intracranial or spinal surgery, gastrointestinal malignancy, or bleeding and coagulopathy.[241] The window of thrombolysis may be extended to 4.5 hours in selected patients.

The narrow window for thrombolysis has limited the number of patients who may benefit from clot removal. Mechanical thrombectomy has recently considerably expanded this window. Previously, endovascular treatment of acute ischemic stroke with large clot in large vessels was restricted to a time period of no more than 6 hours from the time that the patients were last known to be well. Two recent trials demonstrated improved neurologic outcome following internal carotid or proximal MCA thrombectomy in patients up to 16 and 24 hours from the time they were last known well. A key enrollment requirement was the presence of a substantial volume of ischemic, but not yet infarcted, tissue that might be amenable to salvage (substantial mismatch between ischemic and infarcted tissue, indicating that noninfarcted tissue could be salvageable).

The DAWN trial used strictly defined mismatch criteria based upon discrepancy between the clinical neurologic deficit (National Institutes of Health Stroke Scale score) and the volume of infarcted tissue.[242] The DEFUSE 3 trial utilized imaging (computed tomography perfusion or MRI diffusion–perfusion) to identify mismatch between ischemic and infarcted tissue.[243] In both studies, the outcome was more favorable in patients who underwent thrombectomy. These studies will increase the number of patients that are eligible for endovascular treatment following acute ischemic stroke. Consequently, the frequency of involvement of the anesthesiologist in the care of these patients will increase significantly.

The literature on cerebral ischemia and brain protection is vast, and a detailed discourse on this topic is beyond the scope of the present discussion. A number of excellent recent reviews on the subject are available.[244-253]

Considerations Relevant to Complete Global Ischemia (Cardiac Arrest)

Maintaining adequate perfusion pressure after cardiac arrest is of considerable importance. Hypotension developing after resuscitation from cardiac arrest may aggravate the microcirculatory and vasospastic processes occurring at this time and may increase brain damage. A late phase of intracranial hypertension may occur and is due to the development of extensive cerebral edema (probably both vasogenic and cytotoxic edema) associated with brain necrosis. Attempts to control this type of intracranial hypertension with osmotherapy are particularly effective.

Both barbiturates and CCBs have been administered after cardiac arrest. The former are ineffective. In a small cohort (51 patients) of patients after cardiac arrest, nimodipine was shown to improve CBF but not neurologic outcome.[254] In a second trial with approximately 150 patients after cardiac arrest, no overall benefit in neurologic outcome was observed.[255] However, a subset of patients in whom the initiation of advanced life support was delayed for longer than 10 minutes demonstrated improved survival. This single study cannot serve as justification for the administration of nimodipine after cardiac arrest, especially in the face of the unequivocally negative results of the multicenter lidoflazine cardiac arrest study.[256] Once again, the important therapeutic objectives are the maintenance of normocapnia and normotension, normalization of systemic pH, avoidance of hyperoxia,[257] avoidance of hyperthermia, and prevention and treatment of seizures.

Induced mild hypothermia is effective in reducing mortality and morbidity in patients who sustain a cardiac arrest that is followed by altered mental status with a Glasgow Coma Scale score of 7 or less.[258] Induction of mild hypothermia in the range of 32°C to 34°C for a period of approximately 24 hours improved neurologic outcome and survival 6 months after cardiac arrest in comparison with a normothermic group. Mild hypothermia was induced without difficulty. Passive rewarming of patients was slowly accomplished over a period of 8 hours. The incidence of complications was similar to that in the control normothermic group. This important study is one of the first to demonstrate the feasibility and efficacy of induced hypothermia as a treatment to reduce injury from global ischemia. In neonates who sustained hypoxic-ischemic encephalopathy, induction of whole body hypothermia (33.5°C) for 72 hours resulted in a reduced incidence of mortality.[259] Long-term follow-up of patients enrolled in the study confirmed the potentially beneficial effects of mild hypothermia.[260] In many institutions, induced hypothermia has been added to the armamentarium for the treatment of cerebral complications of cardiac arrest or global neonatal hypoxic-ischemic encephalopathy.

Considerations Relevant to Focal (Incomplete) Ischemia

Before discussing individual anesthetics, it should be noted that anesthesia, *per se*, is protective. For undefined reasons, reducing the level of systemic stress associated with a standardized experimental insult results in an improved outcome.[261,262] In reviewing the protection-by-anesthetics literature, readers should be conscious of the possibility that the protective benefit ascribed to an intervention with an anesthetic drug may, in fact, be the product of exaggeration of the injury in a high-stress control state, such as N_2O sedation.

Barbiturates. Numerous demonstrations have revealed the protective efficacy of barbiturates in focal cerebral ischemia in animals,[263-265] and a single demonstration confirmed the effectiveness in humans.[266] The effect has been attributed principally to suppression of CMR. However, the effects of CBF redistribution and free radical scavenging[267] may contribute, and evidence indicates that CMR suppression is not the sole mechanism.[268] Suppression of CMR might logically be expected to be of benefit to brain regions in which oxygen delivery is inadequate to meet normal demands but is sufficient to allow energy consumption by some ongoing electrophysiologic activity (i.e., in which the EEG was abnormal but not flat). Such regions are likely to be limited in size in the setting of focal ischemia, yet several of the animal investigations suggest a very substantial protective effect.[263,264] Review of these experiments reveals that the methods used to monitor and maintain temperature, although accepted at the time, were below the standards that have evolved from a more recent understanding of the effects of both deliberate[269,270] and inadvertent hypothermia. Unrecognized cerebral hypothermia may well have been a factor in some of the cited investigations, and it is therefore possible that the protective efficacy of barbiturates may have been overestimated. Although more recent publications involving suitable temperature control methods do, in fact, indicate a protective effect of barbiturates,[268,271,272] the magnitude of that effect was modest when compared with the results of earlier studies. Barbiturate-induced EEG suppression in an already anesthetized patient may still be logical therapy when it can be applied before or early in the course of a period of temporary focal ischemia (e.g., temporary occlusion during aneurysm surgery). However, the decision to institute such therapy should be made only after considering the risk of the occlusive event, the patient's cardiovascular status, and the physician's willingness to accept the possibility of delayed emergence, together with an objective view of the probable magnitude of the protective effect.

Numerous investigations in animals and humans have failed to demonstrate any protective effect of barbiturates in the setting of global cerebral ischemia (e.g., cardiac arrest).

Because CMR suppression has been the presumed mechanism of effect, barbiturates have traditionally been administered to produce maximal reduction of the CMR (which is nearly complete when EEG burst suppression has been achieved). However, the same protective benefit (expressed as a reduction of infarct volume) was observed in an animal investigation with one third of the burst-suppression dose.[268] This raises a clinically important issue. The various barbiturates (e.g., thiopental, thiamylal, methohexital, pentobarbital) have similar effects on the CMR and have generally been assumed to have equal protective efficacy. However, if the mechanism of protection is a pharmacologic effect other than a reduction in the CMR, then is it reasonable to assume equivalence among the barbiturates? Recent data suggest that the neuroprotective efficacy of barbiturates is not similar. In a direct comparison of three clinically used barbiturates, methohexital and thiopental, but not pentobarbital, reduced injury in an animal model of focal ischemia.[273] These data suggest that mechanisms other than or at least in addition to metabolic suppression may contribute to the protective effect of barbiturates.

Volatile anesthetics. Isoflurane is also a potent suppressant of CMR in the cerebral cortex, and EEG evidence suggestive of a protective effect in humans has been reported.[232] In comparison with the awake or N_2O-fentanyl–anesthetized state, isoflurane is neuroprotective in models of hemispheric,[274] focal,[275] and nearly complete ischemia.[276,277] Of substantial clinical relevance is the observation in a preclinical investigation that isoflurane's neuroprotective efficacy is not sustained.[278] When injury was evaluated 2 days after ischemia, a robust reduction in injury was observed with isoflurane anesthesia. However, by 14 days, this reduction in injury was no longer apparent. These data indicate that neuronal injury continues well into the postischemic recovery period and that the neuroprotective benefit that is evident shortly after ischemia may not persist for the long term. More recent data have shown that isoflurane treatment can improve neuronal survival when the severity of ischemia is limited and the restoration of blood flow after ischemia is complete.[279] The neuroprotective effect of isoflurane is not substantially different from that of other volatile anesthetics. Sevoflurane reduces ischemic injury in animal models of focal[280] and hemispheric ischemia;[281] its efficacy is not different from that of halothane. Desflurane also reduces neuronal injury to the same extent that isoflurane does.[282] The available data therefore suggest that adequate anesthesia, *per se*, may have a protective effect[261,262] versus the awake state, but there does not appear to be any difference in neuroprotective efficacy among the volatile anesthetics.

Xenon. The inert gas xenon exerts its anesthetic action by noncompetitive blockade of NMDAR. As such, it is logical to suspect that it might provide neuroprotection against excitotoxic injury. The neuroprotective efficacy of xenon has been demonstrated against focal ischemia in vivo in mice,[283] and cardiopulmonary bypass–induced cognitive dysfunction in rats.[284] Of interest are observations that simultaneous administration of *subanesthetic* doses of xenon in combination with either hypothermia or isoflurane[285] significantly reduces neuronal injury and improves neurologic function in experimental models; this protective effect was apparent as late as 30 days after injury in a model of neonatal asphyxia. Note should be made, however, that long-term neuroprotection with xenon has not yet been demonstrated in experimental adult subjects. Currently, data are not available to support the specific use of xenon for the purpose of neuroprotection in humans.

Propofol. EEG suppression can also be achieved with clinically feasible doses of propofol. One case series and informal colleague communications indicate that it is being used to provide *protection* during both aneurysm surgery[286] and carotid endarterectomy (CEA). Cerebral infarction was significantly reduced in propofol-anesthetized animals in comparison with awake animals.[287] Direct comparison of propofol to pentobarbital has also demonstrated that cerebral injury after focal ischemia is similar in animals anesthetized with the two drugs.[288] Similar to the situation with volatile anesthetics, initial investigations revealed that propofol protection is not sustained.[289]

Etomidate. Etomidate was proposed as a potential protective anesthetic in the setting of aneurysm surgery.[290] It also produces CMR suppression to an extent equivalent to barbiturates, and similar to the barbiturates, etomidate is an agonist at the (inhibitory) $GABA_A$ receptor. Nonetheless, in an experimental model of focal ischemia, the volume of injury was not reduced by etomidate relative to a 1.2 MAC halothane-anesthetized control group. In fact, the volume of injury with etomidate was significantly larger than that in the control group. In patients subjected to temporary intracranial vessel occlusion, the administration of etomidate results in greater tissue hypoxia and acidosis than equivalent desflurane anesthesia. The aggravation of injury produced by etomidate (an imidazole) may be related to direct binding of NO as a consequence of etomidate-induced hemolysis[291] combined with direct inhibition of the NO synthase enzyme by etomidate. Therefore, no scientific studies support the current use of etomidate for cerebral protection and, in fact, suggest that it may actually be deleterious in the setting of focal ischemia.

Calcium channel antagonists. Orally administering nimodipine (the intravenous preparation is not approved for clinical use in North America) for 21 days beginning as soon as possible after subarachnoid hemorrhage (SAH) is now established clinical practice.[292] Other CCBs have reduced vasospasm after SAH but have not improved patient outcome, suggesting the benefit of nimodipine is a cellular rather than a vascular effect. However, by contrast with SAH, routinely administering nimodipine or any other CCB after neurologic stroke that has occurred in the surgical unit or in any other environment has not yet become standard practice. Despite favorable results in small trials, not all investigations of those who have sustained stroke have confirmed the benefits of nimodipine.[293] Although the administration of CCBs for the management of blood pressure is reasonable, their administration for the sole purpose of neuroprotection is not currently recommended.[241]

Other anesthetics. A remarkable number of anesthetics have shown neuroprotective efficacy in animal studies. However, to date, large-scale randomized trials of a variety of anesthetics in patients with stroke have not demonstrated neuroprotection for any drug. With the exception of tissue plasminogen activator (tPA) for thrombolysis, mechanical thrombectomy, and the CCBs nimodipine and nicardipine for the management of SAH, pharmacologic neuroprotective agents are not available for the treatment of patients with cerebral ischemia. Details about drugs that have undergone clinical trials and those that are currently being investigated in humans can be found at the Stroke Trials Registry (www.strokecenter.org/trials/clinicalstudies) of Washington University in St. Louis.

Cerebral Ischemia: Influence of Physiologic Variables

Cerebral perfusion pressure. Measures designed to augment CBF (an important determinant of energy supply) are also important. In the *ischemic penumbra* (described in the section "Critical Cerebral Blood Flow Thresholds"), small improvements in CBF have the potential to prolong neuronal survival substantially. Maintenance of high-normal CPP can augment collateral perfusion pressure and maintain CBF[294] and has been shown to result in improvement in neurologic function.[295] By contrast, hypotension can reduce CBF and exacerbate injury. In trials of nimodipine in patients with acute stroke, a reduction in blood pressure of 10% to 20% increased the probability of an adverse outcome (either death or dependency) fourfold,[296] thus emphasizing the adverse impact of blood pressure reduction on an injured brain. Therefore, in patients with cerebral ischemia, hypotension should be promptly treated and normotension restored. Although the target MAP should obviously be based on knowledge of a patient's preexisting blood pressure, data to provide specific guidelines are insufficient in humans.[241] In the majority of patients, maintenance of the MAP in the 70 to 80 mm Hg range should be adequate. The available data provide support for reducing blood pressure to less than 180/105 mm Hg in patients with stroke who have been treated with thrombolytic agents in the hope of reducing the incidence of hemorrhage into the ischemic brain.[241] In addition, blood pressure augmentation (after ensuring euvolemia) to a systolic pressure of approximately 180 mm Hg in patients with SAH-induced vasospasm[297] and to a CPP of 60 to 70 mm Hg in patients with traumatic brain injury[298] is reasonable.

Carbon dioxide tension. Hypercapnia has the potential to cause intracerebral steal and may worsen intracellular pH. Despite some support for the occurrence of a favorable so-called Robin Hood or inverse steal, hypocapnia has not generally proved effective in either laboratory or clinical settings. Pending further information and in the absence of a means of verifying the perfusion response to the manipulation of $\mathrm{Pa{CO_2}}$, normocapnia remains standard practice.[298]

Temperature. Hypothermia is the principal cerebral protective technique for circulatory arrest procedures. It unequivocally enhances cerebral tolerance for episodes of ischemia. For deep hypothermia, this effect is largely a function of the reduction in the CMR. Although barbiturates reduce only the component of the CMR associated with electrophysiologic work (approximately 60% of the $\mathrm{CMRO_2}$ in the awake state), hypothermia causes a reduction in both electrophysiologic energy consumption and energy utilization related to the maintenance of cellular integrity; mild hypothermia may preferentially suppress the latter.[299] A substantial number of laboratory studies have demonstrated that mild degree of hypothermia (2°C-4°C) during an episode of ischemia can confer substantial protection as histologically measured.[269,270] In addition, hypothermia initiated in the immediate postischemic period confers a protective benefit.[300]

In light of this dramatic protective effect of mild hypothermia in the laboratory, its use in the surgical setting has been advocated. Proponents of its use argue that hypothermia is readily achieved and not accompanied by significant myocardial depression or arrhythmias. In addition, the patient can be easily rewarmed in the surgical unit after the risk of ischemia has subsided. Results of a pilot study clearly demonstrated a trend toward improved neurologic outcome in hypothermic patients undergoing intracranial aneurysm clipping.[301] Unfortunately, the subsequent definitive Intraoperative Hypothermia for Aneurysm Surgery Trial (IHAST) did not demonstrate any improvement in outcome that could be attributable to hypothermia.[302] However, the majority of the patients in that study had SAH of grades I, II, and III. In addition, the number of patients who had temporary clips applied in excess of 20 minutes was quite small (five to six patients). Consequently, an argument has been advanced that mild hypothermia may be of benefit in patients with high-grade aneurysms or in those in whom the complexity of the aneurysm clipping is such that prolonged temporary clipping may be required. Considering that temperature reduction takes time, the decision to induce hypothermia must be made in advance. It is therefore our view that the therapeutic use of hypothermia may be considered in such high-risk patients.[297]

The application of mild hypothermia after head injury reduced ICP[303] and improved neurologic outcome[304] in pilot trials. Complications attributable to hypothermia were not observed. Two subsequent multicenter trials of hypothermia in patients with head injuries, however, failed to confirm the findings of the pilot studies.[305,306] Induction of mild hypothermia did not improve long-term neurologic outcome.

A number of clinical trials of induced hypothermia in a limited number of patients with stroke have been conducted. To date, these trials have demonstrated the feasibility of inducing hypothermia in the range of 33°C to 35°C, even in patients who are not subjected to endotracheal intubation and mechanical ventilation.[307] Hypothermia was associated with improved ICP and CPP. However, complications, particularly thrombocytopenia, bradycardia, ventricular ectopy, hypotension, and infection, are frequent. In addition, an intractable increase in ICP can occur during rewarming, even if the elevation in temperature is gradual and accomplished over a period of several hours. These side effects attest to the need to conduct randomized trials to evaluate properly the efficacy of mild hypothermia in patients with stroke. At the current time, however, hypothermia for purposes of neuroprotection in the setting of acute ischemic stroke is not recommended.[241]

Data regarding the application of mild hypothermia in survivors of cardiac arrest are more positive. Two recent trials have demonstrated that the induction of hypothermia (32°C-34°C) after successful resuscitation from cardiac arrest resulted in a significantly better neurologic outcome 6 months after the arrest.[258,308] These studies demonstrate the clinical efficacy of hypothermia for the purposes of reducing ischemic cerebral injury and provide indirect support for the use of intraoperative hypothermia in patients who are considered to be at high risk.

By contrast, increases in brain temperature during and after ischemia aggravate injury dramatically.[309] An increase of as little as 1°C can increase injury. Ischemia that normally results in scattered neuronal necrosis produces cerebral infarction when body temperature is elevated. Therefore, avoiding hyperthermia in patients who have suffered an ischemic insult or in those who are at risk for cerebral ischemia seems prudent. In the surgical setting, hyperthermia is seldom a problem. In patients at risk of ischemic cerebral injury, treatment of hyperthermia with antipyretics is currently recommended.[241]

Glucose. Withholding glucose-containing solutions in situations during which cerebral ischemia may occur is now an established practice. The practice is based on numerous demonstrations in animal models of brain and spinal cord ischemia that elevation of plasma glucose before episodes of either complete or incomplete ischemia results in the aggravation of neurologic injury. However, the majority of investigations involved adult animals and that certainty concerning the adverse effects of hyperglycemia in immature subjects, such as neonates, is less.[310] Furthermore, only some[311,312] and not all[313] of the investigations in humans have provided confirmation of an independent effect of serum glucose on neurologic outcome. Nonetheless, in long-term outcome studies, diabetic and nondiabetic hyperglycemia has been shown to be an independent predictor of poor outcome.[312] In the National Institutes of Health–sponsored recombinant tPA stroke trial, hyperglycemia was associated with significantly lower odds for desirable clinical outcomes and a higher incidence of intracranial hemorrhage.[314] These data prompted a randomized clinical trial of the efficacy of insulin administration to patients with acute stroke. The results showed that the administration of insulin to control blood glucose levels in patients with stroke did not improve outcome 3 months after stroke.[315] A recurrent theme in the discussion of these studies is that glucose elevation may be the *result* of the stress associated with a severe insult, either ischemic or traumatic, rather than its *cause.* In addition, the inevitable questions of whether and how quickly immediate pretreatment of an elevated plasma glucose level with insulin reduces risk to normoglycemic levels have not been thoroughly examined. Based on the lack of the benefit of restoration of glucose within the normal range (referred to as “tight” control), the current recommendations, which call for the maintenance of blood glucose values in the 140 to 180 mg/dL range, represent reasonable clinical objectives.[241]

By contrast, hypoglycemia is also associated with cerebral injury. With a gradual reduction in blood glucose values to approximately 40 mg/dL, a shift in EEG frequencies occurs from alpha and beta toward delta and theta.[316] Below a blood glucose level of 20 mg/dL, suppression of the EEG (flat) is observed. Persistence of this level of hypoglycemia results in seizure activity and neuronal injury, particularly to the hippocampus.

Seizures. Seizures cause dramatic increases in CMR and CBF. Sustained seizure activity can significantly augment injury in the damaged brain. Accordingly, seizures should be promptly treated with appropriate antiepileptics in the setting of acute stroke (see the section “Coma and Epilepsy” later in the chapter).[241]

Intravascular volume and hematocrit manipulation. Hemodilution has not proved effective in studies of human stroke. Although hemodilution was often instituted in patients with ischemia associated with vasospasm in SAH with the goal of increasing CBF, current practice is focused more on the maintenance of euvolemia and induction of modest increases in blood pressure rather than on hemodilution. In addition, the data do not currently justify routine hemodilution (a hematocrit of 30%-35% is the theoretic optimum) in patients in whom focal ischemia *might* occur in the surgical unit.[317] An increased hematocrit, because of viscosity effects, reduces CBF.[14] In anticipation of a procedure wherein incomplete ischemia might occur, such as CEA, preoperative phlebotomy should be considered when hematocrit is in excess of 55%.

Hyperoxia. Hypoxia has repeatedly been shown to adversely affect outcome in patients with brain injury from a variety of causes. In an attempt to prevent hypoxia, administration of supplemental oxygen often leads to relative hyperoxia, with $\text{Pa}O_2$ well in excess of normal values. Hyperoxia is associated with vasoconstriction and reduction in microvascular tissue flow, generation of reactive oxygen species, and augmentation of inflammation.[318] This has led to concerns about the potential adverse effects of excess oxygen in the injured brain.[319]

In patients who had sustained cardiac arrest and who were admitted to an intensive care unit after successful recovery of circulation, hyperoxia increased mortality.[320] The threshold $\text{Pa}O_2$ that leads to this increase in mortality is greater than 300 mm Hg; $\text{Pa}O_2$ in the range of 100 to 300 mm Hg was not associated with increased mortality.[321] By contrast, no adverse effect of hyperoxia on long-term outcome (12 months) was apparent among survivors of cardiac arrest.[322] In the setting of head injury, endothelial and tissue edema can reduce diffusion of oxygen to neurons. Hyperoxia improves cerebral metabolism but only in regions of the brain wherein metabolism has been significantly reduced.[323] Other investigations, however, have shown either worse outcomes in hyperoxic patients,[324] especially in those in whom $\text{Pa}O_2$ was excessive (>487 mm Hg), or no effect on long-term outcome.[325] In acute stroke, oxygen administration by nasal cannula, oxygen mask, and endotracheal tube is not associated with adverse outcomes.[326] Similarly, supplemental oxygen administration to patients with SAH does not impact outcomes.[327]

With these conflicting data, it is difficult to draw firm conclusions that can inform clinical decisions. The available data do not allow for the determination of a target $\text{Pa}O_2$, and this is not surprising, given the heterogeneous nature of cerebral injury. Consequently, oxygen administration should be customized in each patient, with the goal being the aggressive treatment of hypoxemia and avoidance of hyperoxia (>300 mm Hg) in patients in whom oxygenation is within normal limits.

Summary of Anesthetics and Neuroprotection

In comparison to the awake or lightly sedated state, the vulnerability of the brain to ischemic injury is reduced under anesthesia. Volatile anesthetics, barbiturates, propofol, xenon, and ketamine reduce injury in experimental models and may reduce injury in comparison with a pure N_2O-narcotic anesthetic. However, direct comparison has not demonstrated the superiority of any one anesthetic (or combination of anesthetics) over another. Therefore, based on the available data, the use of a specific anesthetic or anesthetic regimen for the purpose of brain protection in the clinical setting cannot be recommended.

There is a paucity of information about anesthetic neuroprotection in humans and the lack of clinical trials is understandable, considering the low frequency of stroke and ischemic injury in the perioperative setting. There are, however, a few clinical investigations from which inferences about anesthetic neuroprotection can be made. In the aforementioned IHAST aneurysm trial, a subset of patients received supplemental doses of thiopental, etomidate, or propofol for the purpose of neuroprotection. The neurologic outcome in these patients was no different than those who did not receive these anesthetics.[328] In the general anesthesia versus local anesthesia trial,[329] patients undergoing CEA were randomized to receive either general anesthesia or local anesthesia; in the latter group, patients were lightly sedated but were arousable during surgery. The outcome between the two groups was not different, indicating that the general anesthetic state did not provide any protective benefit.[329] Finally, in a recent retrospective trial of thrombolysis for acute stroke, patients who were anesthetized had a worse outcome than those who were only mildly sedated. Although the worse outcome with general anesthesia was attributed to a lower CPP in that group,[330] the results do not provide evidence of anesthetic neuroprotection. In aggregate, these data suggest that supplemental drugs that produce burst suppression of the EEG do not provide protection in anesthetized patients and that the state of general anesthesia does not improve neurologic outcome measurability.

The neuroprotective efficacy of anesthetic drugs in experimental studies is achieved only by rigorous maintenance of physiologic homeostasis; in fact, the potential for exacerbation of cerebral injury, either traumatic or ischemic, with physiologic mismanagement is significantly greater than the modest protection afforded by pharmacologic drugs—these are important observations. Accordingly, with respect to brain protection, efforts should be focused on the maintenance of physiologic parameters (e.g., perfusion pressure, oxygenation, normocapnia, temperature management, control of hyperglycemia, seizure prophylaxis) within the appropriate ranges and less on pharmacologic or anesthetic drugs to reduce cerebral injury.

Deferring Elective Procedures After Stroke

The risk of extension of cerebral infarction in the event of subsequent anesthesia and surgery has not been studied systematically. In patients who have suffered a stroke, CBF undergoes significant changes. Areas of both high and low CBF occur, and stabilization of regional CBF and CMR is apparent after approximately 2 weeks.[331] Loss of normal vasomotor responses (e.g., CO_2 responsiveness, autoregulation) in the early postinsult period is very common, and these changes persist beyond 2 weeks in a small percentage of patients with stroke. BBB abnormalities, as reflected by the accumulation of CT contrast material or brain scan isotopes, are still present 4 weeks after the insult,[332] and the histologic resolution of large infarcts is not complete for several months. Early CEA after stroke in patients with large strokes and neurologic disability was accompanied by an increased risk of intracerebral hemorrhage.[333] In a recent large cohort study, the occurrence of adverse cardiovascular events, including new stroke and myocardial infarction, was considerably greater in patients who underwent noncardiac surgery within 3 months of having a stroke; the complication rate stabilized 9 months after stroke.[334] Based on early experience with CEA, deferring CEA for at least 6 weeks after stroke is recommended.[333] A 6-week delay should give some assurance of the probable recovery of autoregulation, CO_2 responsiveness, and BBB integrity.

A delay in CEA after stroke, however, poses risks. In patients who have sustained a stroke, the incidence of a second stroke is approximately 12%.[335] The risk of a complete carotid occlusion is considerable with delayed surgery. In addition, early CEA can restore cerebral perfusion to the ischemic penumbra, possibly improving long-term functional recovery. However, the size and location of the infarction should be weighed. A small infarction in the silent cortex may offer wider latitudes than a large lesion that has resulted in a paresis that is still resolving. A small prospective study suggests that in patients with non-disabling stroke, early CEA can be performed safely within 2 weeks of the stroke.[336] Candidates for early CEA after stroke may include patients with relatively small cerebral infarctions, with complete or near complete resolution of neurologic symptoms, and those with ipsilateral carotid artery stenosis.[337] Delaying CEA in patients who have had large strokes with significant neurologic disability, reduced level of consciousness, and displaying a midline shift on the CT scan is generally preferable.

Outcome data to inform the decision about surgery for the patient after stroke, other than CEA, is lacking. With the extrapolation of the information from the CEA studies, pending other information, deferring elective surgery for at least 4 weeks after a cerebral vascular accident and preferably for 6 weeks from the point at which a stable postinsult neurologic state has been achieved seems reasonable.[334]

CHRONIC ARTERIAL HYPERTENSION

A recurrent concern is that of acceptable levels of arterial blood pressure reduction in patients who are chronically hypertensive. Firm guidelines have not been established. However, from the vantage of cerebral well-being, limiting elective MAP reduction 20% to 25% of resting mean levels seems appropriate for both hypertensive and normotensive patients. The same guidelines might apply in both populations, because in chronic hypertension, both the LLA and ULA are shifted to the right with apparently little distortion.[338]

The rationale for a limit of 20% to 25%% is as follows. MAP reductions of 50% in nonanesthetized patients, both normotensive and hypertensive, will commonly produce reversible symptoms of cerebral hypoperfusion.[338,339] Although even greater reductions will probably be tolerated provided that exposures are brief, the hematocrit is reasonable, and the cerebral vasculature is patent, the authors counsel against it. A reduction in the MAP of this magnitude will significantly increase the probability of CPP being close to or below the LLA, thereby reducing cerebrovascular reserve. It has been demonstrated that, on average, a 25% reduction in the MAP will bring both normotensive and hypertensive patients to the LLA.[338] As the reduction in the MAP exceeds 25% of baseline, CBF values will be below normal, albeit, in patients free of occlusive vascular disease, above the threshold for neurophysiologic dysfunction or injury (see Fig. 11.6). However, the physiologic reserve is being encroached upon, thereby leaving little margin for error or for other causes of impaired cerebral oxygen delivery such as low hematocrit or poor collateralization caused by congenital variation or unrecognized cerebrovascular disease.

In animals, treatment of chronic hypertension can restore the LLA to normal.[340, 341] A similar phenomenon has been observed in humans, although restoration was incomplete and had failed to occur after as long as 12 months of treatment in some patients.[338] It is an unexplored possibility that the extent of restoration of the LLA with antihypertensive therapy is agent dependent. Some may restore the LLA more effectively than others. In particular, ACE inhibitors have been shown to decrease the LLA acutely in both normotensive and hypertensive subjects.[342, 343]

Intracranial Hypertension

Control of intracranial hypertension is discussed in detail in Chapter 57.

BRAIN TUMORS

There are few data regarding the physiologic function of intracranial tumors. Measurement of CBF in cerebral tumors with laser Doppler technology revealed that tumors had lower CBF than the normal brain.[344] Autoregulation was occasionally apparent. Vascular responsiveness to changes in $\mathrm{PaO_2}$[345] and $\mathrm{PaCO_2}$[346] are generally preserved in patients with gliomas. Propofol reduces CBF in regions of the brain surrounding the tumor, and quantitatively, the reduction in CBF is similar to that in the contralateral normal hemisphere.[347] Measurement of regional CBF in the area of the tumor might also be a useful predictor of the grade of intracranial gliomas; both regional CBF and regional CBV are greater with high-grade gliomas.[348] Considerable edema is often associated with intracranial tumors, and the radiologic extent of the edema, which presumably represents the extent of abnormal vessel leakiness, correlates with the severity of the elevation in ICP that occurs in association with intubation-related hypertension.[349] Edema formation in the peritumoral region can be characterized as vasogenic with leakage of plasma proteins from the vascular space, hydrocephalic secondary to obstruction of CSF flow, or static as a result of venous obstruction by tumor.[350] Although the precise mechanisms by which edema formation occurs are not clear, the loss of integrity of the tight junctions of components of the BBB, an increased permeability induced by vascular endothelial growth factor expressed by tumors, and an increased expression of leukotriene C4 in peritumoral fluid probably play a role.[351] Osmotherapy with mannitol will effect a reduction in edema; however, with a permeable BBB, mannitol can diffuse into the peritumoral space and lead to rebound edema formation.[350] For acute reduction of ICP in the surgical unit, this concern is not significant. A reduction in osmotherapy-induced neuronal cell volume leads to the intraneuronal accumulation of “idiogenic” osmoles. The consequent increase in intraneuronal osmolarity leads to a reuptake of water into the cell in a compensatory attempt to restore cell volume. This process also contributes to the occurrence of rebound edema. The accumulation of idiogenic osmoles can be reduced significantly by loop diuretics such as bumetanide.[352] Dexamethasone remains the mainstay of treatment of tumor edema; it causes a reduction in edema formation with little effect on edema reabsorption. See Chapter 57 for a complete discussion.

COMA AND EPILEPSY

Regardless of its cause, coma reduces brain metabolism. In the case of lesions occurring in the reticular activating system, the reduction in the CMR probably represents a normal physiologic adjustment to reduced functional activity. During generalized seizure activity, CMR and CBF may increase dramatically.[187] The intensive motor and brain activity associated with generalized seizures leads to the development of systemic and cerebral acidosis, often accompanied by a reduction in arterial oxygenation, an increase in $\mathrm{PaCO_2}$, and peripheral lactic acidosis. If generalized seizure activity continues unabated, then arterial hypotension ensues. With muscular relaxation and measures ensuring adequate oxygenation and ventilation, the systemic acidosis and hypotension can be avoided and the severity of the cerebral acidosis diminished. During relatively brief episodes of continuous seizures, the brain seems able to meet the high metabolic demands.[204] However, even with effective ventilation and maintenance of perfusion pressure, when seizures continue for a prolonged period, they can lead to the development of irreversible neuronal damage.[353] Therapy aimed at interrupting the seizure and restoring a normal balance between cerebral metabolic demand and blood flow is indicated. Barbiturates, benzodiazepines, or other potent anticonvulsants are appropriate. Adequate ventilation, oxygenation, and maintenance of arterial blood pressure are important adjunctive measures. Muscle relaxants must be viewed as purely symptomatic therapy because they do not alter the abnormal cerebral electrical activity. There is, in addition, the concern that muscle paralysis may mask seizure activity, especially when the EEG is not monitored.

The potentially injurious nature of seizures justifies attention to prevention. Practices vary. However, any patient in whom a substantial cortical incision is planned is at risk, and prophylactic anticonvulsants in the perioperative setting should be considered.

Neuromuscular Physiology and Pharmacology

J. A. JEEVENDRA MARTYN and MALIN JONSSON FAGERLUND

KEY POINTS

- The neuromuscular junction contains the distal nerve terminal, Schwann cell, synaptic cleft, and muscle end plate, which together provide an array of receptors and substrates for drug action. Neuromuscular transmission is predominantly dependent on acetylcholine as the natural transmitter. Acetylcholine, when released from the prejunctional nerve terminal, binds to acetylcholine receptors (AChRs) that are present either prejunctionally or postjunctionally within the neuromuscular junction (synapse) and, depending on their structural composition, are classified into the usual muscle subtype AChRs or a variety of neuronal subtype AChRs.
- Muscle relaxants have multiple sites of action. Although the major actions occur by mechanisms and at sites described as agonistic and antagonistic actions at postjunctional receptors for depolarizing and nondepolarizing muscle relaxants (NDMRs), this description of neuromuscular drug action is a simplistic one. Neuromuscular transmission is impeded by NDMRs because they prevent access of acetylcholine to its preferred recognition site on the postjunctional nicotinic AChRs.
- If the concentration of NDMR is increased, another, noncompetitive action—block of the ion channel—is superimposed. The postjunctional paralytic effects of muscle relaxants can be enhanced by the actions of the relaxant on prejunctional AChRs, which modulate the release of acetylcholine. The latter can be documented as *fade* that occurs with increased frequency of stimulation. Fade can also be seen when the postjunctional AChRs alone are functionally blocked (e.g., by bungarotoxin) or when the number of AChRs (e.g., myasthenia gravis) is decreased. Hence, the neuromuscular junction is a complex and dynamic system in which the phenomena produced by drugs are composites of actions that vary with the drug, dose, activity at the nerve terminal and muscle, time after administration, presence of anesthetics or other drugs, and age and condition of the patient.
- Inhibition of acetylcholinesterase enzyme by anticholinesterases (e.g., neostigmine) increases the concentration of acetylcholine in the synaptic cleft, which can compete with and displace the NDMRS and thus reverse the paralysis. These anticholinesterase drugs (e.g., neostigmine) also have other effects, including the nerve terminal and the receptor, by an allosteric mechanism. Acute bolus or prolonged administration of anticholinesterases can have deleterious effects on neuromuscular function in otherwise healthy patients. The modified cyclodextrin, sugammadex, is a novel and innovative class of compound that reverses paralysis of only steroidal muscle relaxants by encapsulation of this series of compounds.
- Depolarizing compounds (e.g., succinylcholine) initially react with the acetylcholine recognition site and, like the transmitter, open AChR ion channels during depolarization of the endplate membrane. Unlike the transmitter, they are not subject to hydrolysis by acetylcholinesterase and therefore remain in the junction. Soon after the administration of succinylcholine, some receptors are desensitized, and, although occupied by the agonist, they do not open to allow current to flow to depolarize the muscle membrane area.
- If the depolarizing relaxant is applied in higher-than-usual concentrations or is allowed to remain at the junction for a long time, then other neuromuscular effects occur; depolarizing relaxants in higher concentrations have effects on prejunctional structures, and the combination of prejunctional and postjunctional effects plus secondary ones on muscle and nerve homeostasis results in the complicated phenomenon known as *phase II block*. Some of the other drugs used clinically (e.g., Botox) have effects on the motor nerve and therefore indirectly on muscle. Systemic infection with clostridial toxins (*Clostridium botulinum*, gas gangrene) can lead to systemic paralysis as a result of decreased release of acetylcholine from the nerve terminal. NDMRs administered for 24 hours or longer can have effects on the postsynaptic receptor and simulate denervation state (chemical denervation) manifested by upregulated postsynaptic AChRs. Magnesium given to preeclamptic mothers decreases the release of acetylcholine with a potential for muscle weakness in the mother or newborn. In recognizing these sites and mechanisms, we begin to bring our theoretical knowledge closer to explaining the phenomena observed when these drugs are exposed to living humans.

Continued

- Contemporary research work has focused on the control of AChR expression on the postjunctional membrane in normal and diseased states. The presence or absence of the conventional mature and immature isoforms seems to complicate matters further. In certain pathologic states (e.g., denervation, stroke, sepsis, burns, immobilization, chronic use of NDMRs), AChRs are upregulated, with increased expression of the immature isoform and *de-novo* expression of the nicotinic α7 acetylcholine receptors (α7 AChRs). Altered functional and pharmacologic characteristics of the immature (fetal or γ-subunit–containing receptors) and α7 AChRs expressed in pathologic muscle wasting conditions result in increased sensitivity to succinylcholine with hyperkalemia and resistance (insensitivity) to NDMRs.
- An area of increasing attention is control of the expression of mature versus the other two receptor isoforms (immature γ- and α7 AChRs on the synapse). Re-expression of the immature γ- and α7 AChRs is probably related to aberrant growth factor signaling.
- Genetic mutations in the AChRs, that result in prolonged or fast open-channel time, can lead to a myasthenia-like state, even in the presence of normal receptor numbers. The weakness is usually related to ineffective depolarization or to the altered open-channel time, or to both.

Although cholinergic neurotransmission at the neuromuscular junction is the most widely studied synapse within the nervous system, complete knowledge of its workings has not yet been achieved. The physiology of neuromuscular transmission could be analyzed and understood at the simplest level by using the classic model of nerve signaling to muscle through the acetylcholine receptor (AChR). The mammalian neuromuscular junction and the nicotinic AChRs are the prototypical and most extensively studied synapse and receptor, respectively. Research has provided more detailed information on processes that, within the classic scheme, can modify neurotransmission and response to drugs. One example is the role of qualitative or quantitative changes in AChRs that modify neurotransmission and the response to drugs.[1-3] In myasthenia gravis, for example, the decrease in AChRs results in decreased efficiency of neurotransmission (and therefore muscle weakness)[4] and altered sensitivity to neuromuscular relaxants.[3] Another example is the importance of nerve-related (prejunctional) changes that alter neurotransmission and the response to muscle relaxants.[5-7] Yet, muscle relaxants act in ways that are not encompassed by the classic scheme of a unitary site of action. The observation that muscle relaxants can have prejunctional effects[5] or that some muscle relaxants can also have agonist-like stimulatory actions on the receptor,[8] whereas others have effects not explainable by purely postsynaptic actions on muscle,[9-11] has provided new insight into some previously unexplained observations. Although muscle relaxants are known to have effects on the presynaptic and postsynaptic receptors of the neuromuscular junction, recent evidence indicates that they can react with nicotinic and muscarinic AChRs other than those in muscle, including receptors on the carotid body, on the vagus to the heart, and on bronchial smooth muscle.[9-13] Although this multifaceted action-response scheme makes the physiologic and pharmacologic neurotransmission more complex, these added insights also bring experimentally derived knowledge much closer to clinical observations. This review dwells on the basic physiology and anesthesia-related pharmacology of the neuromuscular junction. Several reviews that provide more detailed insight into the physiological and pathological processes that alter function and pharmacology of the neuromuscular junction are available for the initiated reader.[14-19]

Neuromuscular Transmission

Neuromuscular transmission occurs by a fairly simple and straightforward mechanism. The nerve synthesizes acetylcholine and stores it in small, uniformly sized packages called *vesicles*. Stimulation of the nerve causes these vesicles to migrate to the surface of the nerve, rupture, and discharge acetylcholine into the cleft separating the nerve from muscle. AChRs in the end plate of the muscle respond by opening their channels for influx of sodium ions into the muscle to depolarize the muscle. The end-plate potential created is continued along the muscle membrane by the opening of sodium channels present throughout the muscle membrane to initiate a muscle contraction.[16,17] The acetylcholine immediately detaches from the receptor and is destroyed by the enzyme, acetylcholinesterase, which is also present in the cleft. Exogenous drugs that activate the nicotinic AChR, that is, agonists such as depolarizing muscle relaxants (e.g., succinylcholine or nicotine), can also act on these receptors and mimic the effect of acetylcholine and cause depolarization of the end plate. Nondepolarizing muscle relaxants (NDMRs) also act on the receptors, but they prevent acetylcholine from binding to the receptor and thus prevent depolarization by agonists. Because these NDMRs prevent the action of agonists (e.g., acetylcholine, carbachol, succinylcholine), they belong to the class of compounds known as *antagonists* at the muscle AChRs. Other compounds, frequently called *reversal drugs* or antagonists of neuromuscular paralysis (e.g., neostigmine, prostigmine), inhibit acetylcholinesterase and therefore impair the hydrolysis of acetylcholine. The increased accumulation of undegraded acetylcholine can effectively compete with NDMRs and thereby displace the latter from the receptor (i.e., law of mass action) and antagonize the effects of NDMRs.

MORPHOLOGY

The neuromuscular junction is specialized on both the nerve side and on the muscle side to transmit and receive chemical messages.[15-19] Each motor neuron runs without interruption from the ventral horn of the spinal cord or medulla to the neuromuscular junction as a large, myelinated axon (Fig. 12.1*A*). As the motor neuron approaches the muscle, the neuron repeatedly branches to contact many muscle

Fig. 12.1 Structure of the adult neuromuscular junction shows the three cells that constitute the synapse: the motor neuron (i.e., nerve terminal), muscle fiber, and Schwann cell. (A) The motor nerve originates in the ventral horn of the spinal cord or brainstem. (B) As the nerve approaches its muscle fibers and before attaching itself to the surface of the muscle fiber, the nerve divides into branches that innervate many individual muscle fibers. (C) Each muscle receives only one synapse. The motor nerve loses its myelin and further subdivides into many presynaptic boutons to terminate on the surface of the muscle fiber. (D) The nerve terminal, covered by Schwann cells, has vesicles clustered about the membrane thickenings, which are the active zones, toward its synaptic side and mitochondria and microtubules toward its other side. A synaptic gutter or cleft made up of a primary and many secondary clefts separate the nerve from the muscle. The muscle surface is corrugated, and dense areas on the shoulders of each fold contain acetylcholine receptors. Sodium (Na^+) channels are present at the bottom of the clefts and throughout the muscle membrane. The acetylcholinesterase and proteins and proteoglycans that stabilize the neuromuscular junction are present in the synaptic clefts.

cells and gather them into a functional group known as a *motor unit* (see Fig. 12.1*B*). The architecture of the nerve terminal is quite different from that of the rest of the axon. As the terminal reaches the muscle fiber, it loses its myelin, forms a spray of terminal branches against the muscle surface, and is covered by Schwann cells. This arrangement conforms to the architecture on the synaptic area of the muscle membrane (see Fig. 12.1*C*). The nerve is separated from the surface of the muscle by a gap of approximately 50 nm, called the *junctional cleft* or *synaptic cleft*. The nerve and muscle are held in tight alignment by protein filaments called *basal lamina* that span the cleft between the nerve and end plate. The muscle surface is heavily corrugated, with deep invaginations of the junctional cleft—the primary and secondary clefts—between the folds in the muscle membrane; thus, the end plate's total surface area is very large. The depths of the folds also vary between muscle types and species. Human neuromuscular junctions, relative to muscle size, are smaller than those of the mouse, although the junctions are located on muscle fibers that are much larger. Human junctions have longer junctional foldings and deeper gutters.[14,17] The sodium channels, which propagate the wave of depolarization, are located in the depths of the folds (see Fig. 12.1*D*). The shoulders of the folds are densely populated with AChRs, approximately 5 million of them in each junction. AChRs are sparse in the depths between the folds.

The trophic function of the nerve is vital for the development and maintenance of adequate neuromuscular function. Before birth, each muscle cell commonly has contacts with several nerves and has several neuromuscular junctions.[14,19] At birth, all but one of the nerves retract, and a single end plate remains (see section on "Neuromuscular Junction at the Extremes of Age"). Once formed, the nerve-muscle contact, especially the end plate, is durable. Even if the original nerve dies, the one replacing it innervates exactly the same region of the muscle. The nerve endings on fast muscles are larger and more complicated than those on slow muscles. The reason for this is unclear. These differences in the nerve endings on muscle surfaces may play a role in the difference in response of fast- and slow-twitch muscle fibers to muscle relaxants.

Because all the muscle cells in a unit are excited by a single neuron, stimulation of the nerve electrically or by an action potential originating from the ventral horn or by any agonist, including depolarizing relaxants (e.g., succinylcholine), causes all muscle cells in the motor unit to contract synchronously. Synchronous contraction of the cells in a motor unit is called *fasciculation* and is often vigorous enough to be observed through the skin. Although most adult human muscles have only one neuromuscular junction per cell, an important exception is some of the cells in extraocular muscles. The extraocular muscles are *tonic* muscles, and, unlike other mammalian striated muscles, they are multiply innervated with several neuromuscular junctions strung along the surface of each muscle fiber.[20-23] Quite in contrast to other muscles, even the adult ocular muscle contains mature and immature fetal receptors (see section on "Biology of Prejunctional and Postjunctional Nicotinic Acetylcholine Receptors") segregated into distinct synapses on different fibers.[20-22] The ocular muscles slowly contract and relax rather than quickly as do other striated muscles; they can maintain a steady contraction, or contracture, the strength of which is proportional to the stimulus received. Physiologically, this specialization apparently holds the eye steadily in position. Ocular muscles are important to an anesthesiologist because depolarizing muscle relaxants (e.g., succinylcholine) affect them differently than they do on most skeletal muscles. Instead of causing a brief contraction, followed by paralysis, the depolarizing drug causes a long-lasting contracture response that pulls the eye against the orbit and could contribute to an increase in intraocular fluid pressure.[22,23] The clinical significance of the succinylcholine-induced increase in intraocular pressure has been questioned. Although many textbooks invoke the reported extrusion of intraocular contents with succinylcholine, the basis for this effect seems to be anecdotal.[24] Clinical studies, however, have indicated that succinylcholine-induced contractions of the extraocular muscles can last as long as 1 to 2 minutes and isometric tensions larger than 12 g can develop for each extraocular muscle.[23] Thus, succinylcholine probably should not be given to patients with open eye injuries.

The perijunctional zone is the area of muscle immediately beyond the junctional area and is critical to the function of the neuromuscular junction. The perijunctional zone contains a mixture of receptors, including a smaller density of AChRs and a high density of sodium channels (see Fig. 12.1*D*). The admixture enhances the capacity of the perijunctional zone to respond to the depolarization (i.e., end-plate potential) produced by the AChRs and to transduce it into the wave of depolarization that travels along the muscle to initiate muscle contraction. The density of sodium channels in the perijunctional area is richer than in more distal parts of the muscle membrane.[25,26] The perijunctional zone is close enough to the nerve ending to be influenced by transmitter released from it. Moreover, special variants (i.e., isoforms) of receptors and sodium channels can appear in this area at different stages of life and in response to abnormal decreases in nerve activity (see section on "Biology of Prejunctional and Postjunctional Nicotinic Acetylcholine Receptors"). Congenital abnormalities in the AChRs or in the sodium and calcium channels (i.e., mutations) are also known.[25-27] These variabilities seem to contribute to the differences in response to relaxants that are observed in patients with different pathologic conditions and ages.[17,27]

QUANTAL THEORY

The contents of a nerve ending are not homogeneous. As illustrated in Figs. 12.1*C* and 12.2, vesicles are congregated in the portion toward the junctional surface, whereas microtubules, mitochondria, and other support structures are located toward the opposite side. The vesicles containing transmitter are ordered in repeating clusters alongside small, thickened, electron-dense patches of membrane referred to as *active zones* or *release sites*. This thickened area is a cross section of a band running across the width of the synaptic surface of the nerve ending that is believed to be the structure to which vesicles attach (active zones) before they rupture into the junctional cleft (see section on "Process of Exocytosis"). High-resolution scanning electron micrographs reveal small protein particles arranged alongside the active zone between vesicles. These particles are believed to be special channels—voltage-gated calcium channels—that allow calcium to enter the nerve and cause the release of vesicles.[28,29] The rapidity with which the neurotransmitter is released (200 μs) suggests that voltage-gated calcium channels are close to the release sites. Proteomic studies suggest that at least 26 genes encode presynaptic proteins, and mutations in 12 of them cause defects in presynaptic structure that can lead to decreased acetylcholine release and muscle weakness.[30] These defects can be related to exocytosis, endocytosis, formation of active and periactive zones, vesicle transport, and neuropeptide modulation.[30]

When observing the electrophysiologic activity of a skeletal muscle, small, spontaneous depolarizing potentials at neuromuscular junctions can be seen. These potentials have only one hundredth the amplitude of the evoked end-plate potential produced when the motor nerve is stimulated. Except for amplitude, these potentials resemble the end-plate potential in the time course and manner they are affected by drugs. These small-amplitude potentials are called *miniature end-plate potentials* (MEPPs). Statistical analysis led to the conclusion that they are unitary responses; that is, there is a minimum size for the MEPP, and the sizes of all MEPPs are equal to or multiples of this minimum size. Because MEPPs are too large to be produced by a single molecule of acetylcholine, it was deduced that they are produced by uniformly sized packages, or quanta, of transmitter released from the

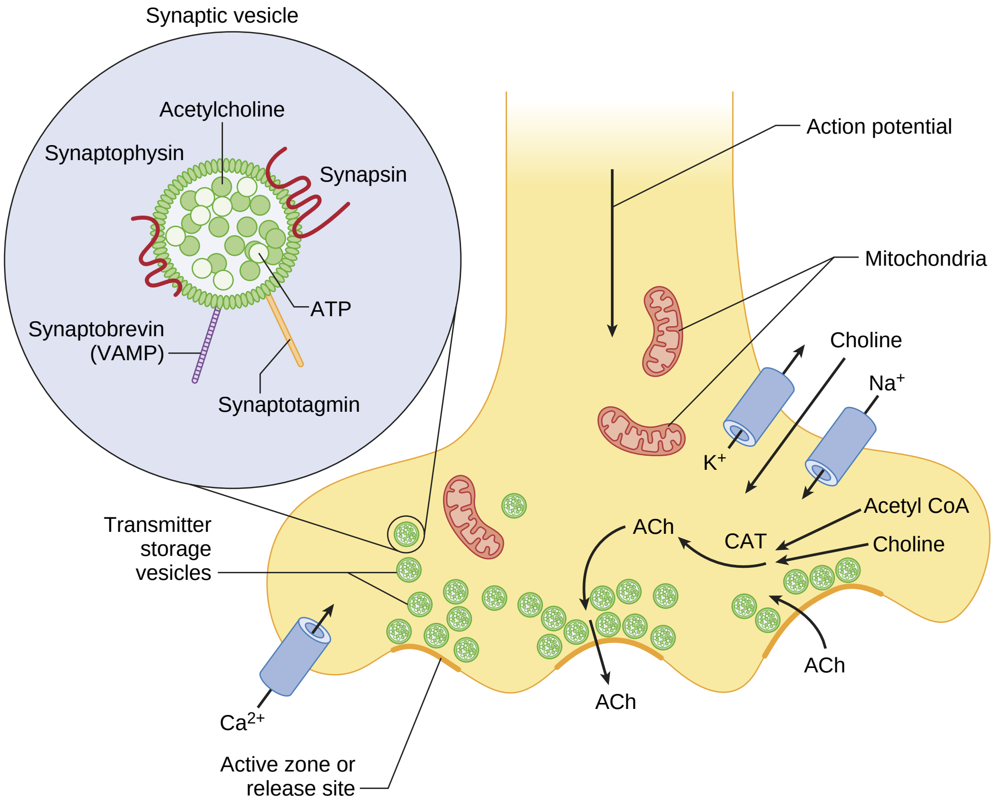

Fig. 12.2 The working of a chemical synapse, the motor nerve ending, including some of the apparatus for synthesis of transmitter, is illustrated. The large intracellular structures are mitochondria. Acetylcholine *(ACh)*, synthesized from choline and acetate by acetyl coenzyme A *(CoA)*, is transported into coated vesicles, which are moved to release sites. A presynaptic action potential that triggers the influx of calcium (Ca^{2+}) through specialized proteins (i.e., Ca^{2+} channels) causes the vesicles to fuse with the membrane and discharge transmitter. Membrane from the vesicle is retracted from the nerve membrane and recycled. Each vesicle can undergo various degrees of release of contents—from incomplete to complete. The transmitter is inactivated by diffusion, catabolism, or reuptake. The inset provides a magnified view of a synaptic vesicle. Quanta of ACh, together with adenosine triphosphate *(ATP)*, are stored in the vesicle and covered by vesicle membrane proteins. Synaptophysin is a glycoprotein component of the vesicle membrane. Synaptotagmin is the vesicle's calcium sensor. Phosphorylation of another membrane protein, synapsin, facilitates vesicular trafficking to the release site. Synaptobrevin (vesicle-associated membrane protein *[VAMP]*) is a SNARE protein involved in attaching the vesicle to the release-site proteins at the nerve terminal (see also Fig. 12.3). *CAT,* Choline acetyltransferase; *K^+*, potassium; *Na^+*, sodium.

nerve (in the absence of stimulation). The stimulus-evoked end-plate potential is the additive depolarization produced by the synchronous discharge of quanta from several hundred vesicles. The action potential that is propagated to the nerve ending allows the entry of calcium into the nerve through voltage-gated calcium channels, which causes vesicles to migrate to the active zone, fuse with the neural membrane at release sites, and discharge their acetylcholine into the junctional cleft.[28,29] Because the release sites are located immediately opposite the receptors on the postjunctional surface, little transmitter is wasted, and the response of the muscle is coupled directly with the signal from the nerve.[17,28]

Alignment of the presynaptic receptor site is achieved by adhesion molecules or specific cell-surface proteins located on both sides of the synapse that grip each other across the synaptic cleft and hold together the prejunctional and postjunctional synaptic apparatuses.[14,19,31] One such protein implicated in synapse adhesion is neurexin, which binds to neuroligins on the postsynaptic membrane. The amount of acetylcholine released by each nerve impulse is large, at least 200 quanta of approximately 5000 molecules each, and the number of AChRs activated by transmitter released by a nerve impulse is also large, approximately 500,000 molecules. The ions (mostly sodium and some calcium) that flow through the channels of activated (open) AChRs cause maximum depolarization of the end plate, which results in an end-plate potential that is greater than the threshold for stimulation of the muscle. This system is extremely vigorous. The signal is carried by more molecules of transmitter than are needed, and they evoke a response that is larger than needed. At the same time, only a small fraction of the available vesicles and receptors or channels are used to send each signal. Consequently, transmission has a substantial margin of safety, and, at the same time, the system has substantial capacity in reserve.[16-18,32]

Neuromuscular Junction

FORMATION OF NEUROTRANSMITTER AT MOTOR NERVE ENDINGS

The axon of the motor nerve carries electrical signals from the spinal cord to muscles and has all the biochemical apparatus needed to transform the electrical signal into a chemical one. All the ion channels, enzymes, other proteins, macromolecules, and membrane components needed by the nerve ending to synthesize, store, and release acetylcholine and other trophic factors are made in the cell body and transmitted to the nerve ending by axonal transport (see Fig. 12.2).[15,28,29] The simple molecules, choline and acetate, are obtained from the environment of the nerve ending, where choline is transported by a special system from extracellular fluid to the cytoplasm and acetate in the form of acetyl coenzyme A from mitochondria. The enzyme choline acetyltransferase brings about the reaction of choline and acetate to form acetylcholine. After synthesis, acetylcholine is stored in cytoplasm until it is transported and incorporated into vesicles, which are better positioned for release when an action potential reaches the nerve terminal.

NERVE ACTION POTENTIAL

During a nerve action potential, sodium from outside flows across the membrane, and the resulting depolarizing voltage opens the calcium channels, which allows entry of calcium ions into the nerve and causes acetylcholine to be released. A nerve action potential is the normal activator that releases the transmitter acetylcholine. The number of quanta released by a stimulated nerve is greatly influenced by the concentration of ionized calcium in extracellular fluid. If calcium is not present, then depolarization of the nerve, even by electrical stimulation, will not produce the release of transmitter. Doubling the extracellular calcium results in a 16-fold increase in the quantal content of an end-plate potential.[33] The calcium current persists until the membrane potential is returned to normal by outward fluxes of potassium from inside the nerve cell. Along with calcium channels on the nerve terminal are potassium channels, including the voltage-gated and calcium-activated potassium channels, whose function is to limit entry of calcium into the nerve and therefore depolarization.[26,32] The calcium current can be prolonged by potassium channel blockers (e.g., 4-aminopyridine, tetraethylammonium), which slow or prevent the efflux of potassium out of the nerve. The increase in quantal content produced in this way can reach astounding proportions.[17,34] An effect of increasing calcium in the nerve ending is also clinically observed as the so-called *posttetanic potentiation* (PTP), which occurs after a nerve of a patient paralyzed with an NDMR is stimulated at high, tetanic frequencies. Calcium enters the nerve with every stimulus, but it accumulates during the tetanic period because it cannot be excreted as quickly as the nerve is stimulated. Because the nerve ending contains more than the normal amount of calcium for some time after the tetanus, a stimulus applied to the nerve during this time causes the release of more than the normal amount of acetylcholine. The abnormally large amount of acetylcholine antagonizes the relaxant (temporarily) and causes the characteristic increase in the size of the twitch (i.e., post tetanic facilitation).

Calcium enters the nerve through specialized proteins called *calcium channels*.[15,35] Of the several types of calcium channels, two seem to be important for the release of transmitter: P channels and the slower L channels. P channels, probably the type responsible for the normal release of transmitter, are found only in nerve terminals.[13,35] In motor nerve endings, the calcium channels are located immediately adjacent to the active zones (see Fig 12.2). They are voltage-dependent and are opened and closed by changes in membrane voltage caused by the nerve action potential. In addition to calcium channels, several forms of potassium channels are present in the nerve terminal, including voltage-gated and calcium-activated potassium channels. Potassium channels limit the duration of nerve terminal depolarization and hence the entry of calcium and the release of transmitter.[26] Alterations in entry of calcium into the nerve ending can also alter the release of transmitter. The Eaton-Lambert myasthenic syndrome, which should not be confused with myasthenia gravis, is an acquired autoimmune disease in which antibodies are directed against voltage-gated calcium channels at nerve endings.[36] In this syndrome, decreased function of the calcium channel causes decreased release of transmitter, which results in inadequate depolarization and muscle weakness. Patients with Eaton-Lambert myasthenic syndrome exhibit increased sensitivity to depolarizing and nondepolarizing relaxants.[37]

Higher-than-normal concentrations of bivalent inorganic cations (e.g., magnesium, cadmium, manganese) can also block the entry of calcium through P channels and profoundly impair neuromuscular transmission. This mechanism is behind the typical muscle weakness and potentiation of the effect of muscle relaxants in a mother and fetus when magnesium sulfate is administered to treat preeclampsia. P channels, however, are not affected by calcium entry-blocking drugs such as verapamil, diltiazem, and nifedipine. These drugs have profound effects on the slower L channels present in the cardiovascular system. As a result, the L-type calcium channel blockers have no significant effect at therapeutic doses on the normal release of acetylcholine or on the strength of normal neuromuscular transmission. However, calcium entry-blocking drugs may increase the block in neuromuscular transmission induced by NDMRs. The effect is small, and not all investigators have been able to observe it. The explanation may lie in the fact that nerve endings also contain L-type calcium channels. The effects of calcium channels on depolarizing relaxants, if any, are unknown.

SYNAPTIC VESICLES AND RECYCLING

Two pools of vesicles seem to release acetylcholine, a readily releasable pool and a reserve pool, sometimes called VP1 and VP2, respectively.[38,39] Electron microscopic studies have demonstrated that the majority of synaptic vesicles (VP1) are sequestered in the reserve pool and tethered to the cytoskeleton in a filamentous network made up of primarily actin, synapsin (an actin-binding protein), synaptotagmin, and spectrin.[38,39] Vesicles in VP2 are a bit smaller and limited to an area very close to the nerve membrane, where they are bound to the active zones. These vesicles are the ones that ordinarily release transmitter. Release occurs when calcium ions enter the nerve through the P channels lined up on the sides of the active zones by soluble *N*-ethylmaleimide-sensitive attachment protein receptor (SNARE) proteins.[38,39] The SNARE proteins are involved in fusion, docking, and release of acetylcholine at the active zone. Calcium needs to move only a very short distance (i.e., a few atomic radii) to encounter a vesicle and activate the proteins in the vesicle wall involved in a process known as *docking* (see section on "Process of Exocytosis").[39] The activated proteins seem to react with the nerve membrane to form a pore through which the vesicle discharges its acetylcholine into the junctional cleft. Studies using fluorescent proteins

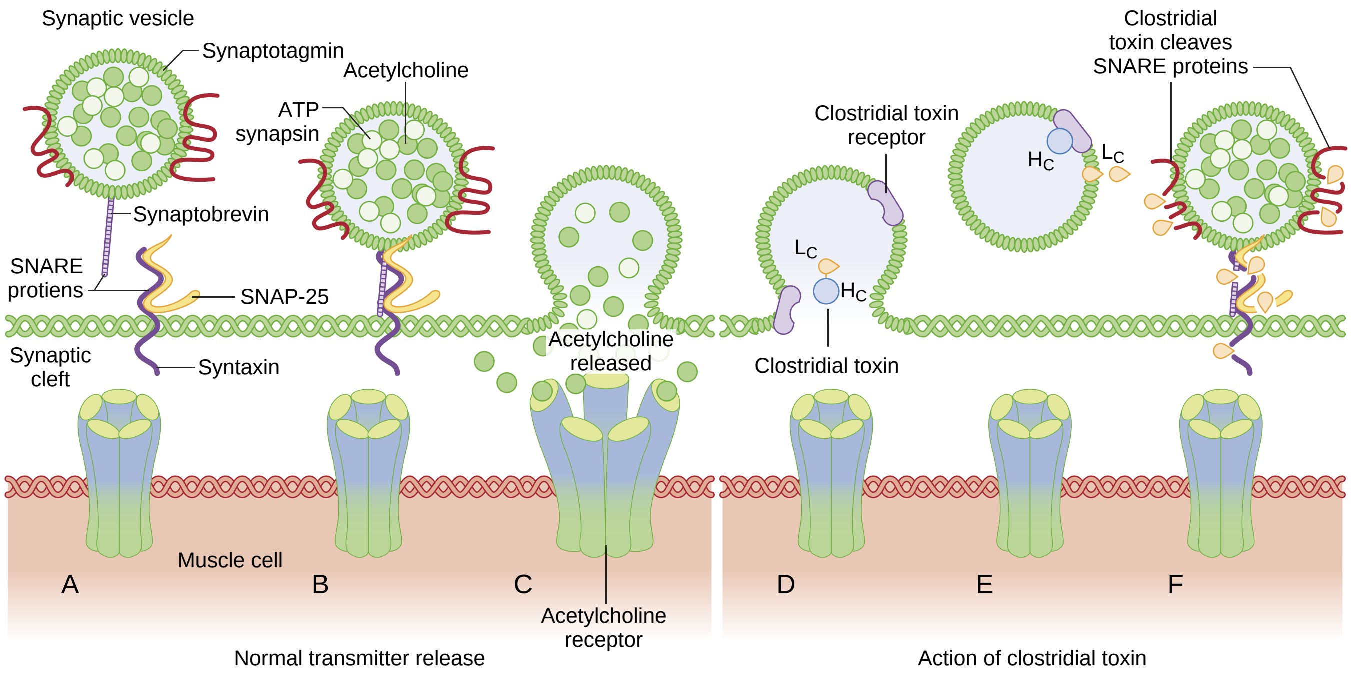

Fig. 12.3 Model of protein-mediated membrane fusion and exocytosis. (A) Release of acetylcholine from vesicles is mediated by a series of proteins collectively called *SNARE* proteins. Synaptotagmin is the neuronal calcium receptor that detects entry of calcium. Synaptobrevin (i.e., vesicle-associated membrane protein [VAMP]) is a filament-like protein on the vesicle. (B) During depolarization and entry of calcium, synapsin is also present on the vesicle membrane. Synaptobrevin on the vesicle unfolds and forms a ternary complex with syntaxin/SNAP-25 on the nerve terminal membrane. (C) Assembly of the ternary complex forces the vesicle in close apposition to the nerve membrane at the active zone with release of its contents, acetylcholine. The fusion is disassembled, and the vesicle is recycled. (D) Clostridial toxin, botulinum, inhibits the release of acetylcholine and causes paralysis of muscles. The toxin consists of a light chain *(L_c)* and a heavy chain *(H_c)*. The first stage in intoxication is the interaction of the toxin with a thus far unidentified receptor. (E) This interaction is followed by internalization of the toxin within the vesicle and the release of the L_c of toxin from the vesicle. (F) The liberated L_c cleaves a variety of SNARE proteins, depending on the type of toxin released, thereby preventing assembly of the fusion complex and thus blocking the release of acetylcholine. *ATP*, Adenosine triphosphate; *SNAP-25*, synaptosome-associated protein of 25-kd.

have visualized how synaptic vesicles fuse with release sites and release their contents, which are then retrieved. Some vesicles stay open briefly before retrieval and do not completely collapse into the surface membrane (“kiss and run”). Others stay open longer and probably do not completely collapse (“compensatory”). Still others completely collapse and are not retrieved until another stimulus is delivered (“stranded”).[38,39]

The larger reserve (VP1) vesicles, from their position deep from the nerve ending and firmly tethered to the cytoskeleton by many proteins, including actin, synapsin (an actin-binding protein), synaptotagmin, and spectrin,[37,38] may be moved to the readily releasable store to replace worn-out vesicles or to participate in transmission when the nerve is called on to work especially hard (e.g., when it is stimulated at very high frequencies or for a very long time). Under such strenuous circumstances, calcium may penetrate more deeply than normal into the nerve or may enter through L channels to activate calcium-dependent enzymes that break the synapsin links holding the vesicles to the cytoskeleton, thereby allowing the vesicles to be moved to the release sites. Repeated stimulation requires the nerve ending to replenish its store of vesicles filled with transmitter, a process known as *mobilization*. The term is commonly applied to the aggregate of all steps involved in maintaining the nerve ending’s capacity to release transmitter—everything from the acquisition of choline and the synthesis of acetate to the movement of filled vesicles to release sites. Uptake of choline and the activity of choline acetyltransferase, the enzyme that synthesizes acetylcholine, are probably the rate-limiting steps.[15,29]

PROCESS OF EXOCYTOSIS

The readily releasable pool of synaptic vesicles constitutes the vesicles directly available for release. During an action potential and calcium influx, neurotransmitter is released. Studies have shed some light on the inner workings by which the vesicle releases its contents. The whole process is called *exocytosis*. The SNARE proteins include (Fig. 12.3*A*) the synaptic-vesicle protein, synaptobrevin; the plasmalemma-associated protein, syntaxin; and the synaptosome-associated protein of 25-kd (SNAP-25).[38,39] The current model of protein-mediated membrane fusion in exocytosis is as follows. When there is an action potential and calcium ions enter, synapsin becomes phosphorylated, which frees the vesicle from its attachment to the cytoskeleton. Syntaxin and SNAP-25 are complexes attached to the plasma membrane. After the initial contact, the synaptobrevin on the vesicle forms a ternary complex with syntaxin and SNAP-25. Synaptotagmin is the protein on the vesicular membrane that acts as a calcium sensor, localizes the synaptic vesicles to synaptic zones rich in calcium channels, and stabilizes the vesicles in the docked state.[38] Assembly of the ternary complex forces the vesicle to move close to the underlying nerve terminal membrane (i.e., the active zone), and the vesicle is then ready for release (see Fig. 12.3*B*). The close proximity of release sites, calcium channels, and synaptic vesicles and the use of the calcium sensor lead to a burst of release of new transmitter synchronous with the stimulus (see Fig. 12.3*C*).[37-40] The vesicle can release part or all of its contents, some of which can be recycled to form new vesicles as previously described ("kiss and run," "compensatory," "stranded").[37-40]

Botulinum neurotoxin selectively digests one or all these SNARE proteins and blocks exocytosis of the vesicles,[41,42] which ultimately results in muscle weakness or more profound muscle paralysis. This toxin may produce a partial or complete chemical denervation. Botulinum toxin is therapeutically used to treat spasticity or spasm in several neurologic and surgical diseases, to prevent hyperhidrosis in patients with excessive sweating, and cosmetically to correct wrinkles.[43,44] Botulinum toxin consists of two protein segments known as heavy and light chains (see Fig. 12.3*D* and *E*). The heavy chain interacts with lipid molecules called *polysialogangliosides* in the cell membrane and synaptotagmin on the vesicle to enter the vesicle. Once in the vesicle, the light chain inactivates neuromuscular transmission by breakdown and thereby inhibits the function of SNARE proteins (see Fig. 12.3*F*). Some reports indicate an increased incidence of clostridial infections in both Canada and the United States, with *Clostridium botulinum* infection being particularly common after traumatic injuries, in drug abusers, and after musculoskeletal allografts.[6,7] Thus, systemic paralysis can occur after clostridial infection. Local injection for therapeutic purposes will usually result in localized paresis, although systemic effects have been reported.[7,45]

ACETYLCHOLINESTERASE

The acetylcholine released from the nerve diffuses across the junctional cleft and reacts with nicotinic AChRs in the end plate to initiate muscle contraction. Transmitter molecules that do not immediately react with a nicotinic AChR or those released after binding to the receptor are almost instantly destroyed by acetylcholinesterase in the junctional cleft. Acetylcholinesterase at the junction is the asymmetric or A12 form protein made in the muscle under the end plate. Acetylcholinesterase (enzyme classification 3.1.1.7) is type B carboxylesterase enzyme. A smaller concentration of the enzyme is found in the extrajunctional area. The enzyme is secreted from the muscle but remains attached to it by thin stalks of collagen fastened to the basement membrane.[15,37] Most of the molecules of acetylcholine released from the nerve initially pass between the enzymes to reach the postjunctional receptors; however, as they are released from the receptors, they invariably encounter acetylcholinesterase and are destroyed. Under normal circumstances, a molecule of acetylcholine reacts with only one receptor before it is hydrolyzed. Acetylcholine is a potent messenger, but its actions are very short lived because it is destroyed in less than 1 ms after it is released.

Some congenital and acquired diseases are caused by altered activity of acetylcholinesterase. The congenital absence of the secreted enzyme (in knock-out mice) leads to impaired maintenance of the motor neuronal system and organization of nerve terminal branches.[46] Many syndromes caused by congenital abnormalities in cholinesterase function have been described and result in neuromuscular disorders whose symptoms and signs usually resemble those of myasthenia gravis or myasthenic syndromes.[27,47] Denervation decreases acetylcholinesterase at the junctional and extrajunctional areas.[37] Other acquired diseases involving cholinesterases are related to chronic inhibition of acetylcholinesterase by organophosphate pesticides or nerve gas (e.g., sarin) or to chronic pyridostigmine therapy given as prophylaxis against nerve gas poisoning.[48,49] Symptoms ranging from chronic fatigue to muscle weakness have been attributed to chronic cholinesterase inhibition, thus underscoring the importance of acetylcholinesterase in normal and abnormal neuromuscular function. A rodent study confirms that the muscle weakness associated with chronic pyridostigmine therapy is related to both AChRs downregulation and to receptor-independent factors.[50]

POSTJUNCTIONAL ACETYLCHOLINE RECEPTORS

The similarity of AChRs among many species and the abundance of AChRs from *Torpedo electric fish* have greatly facilitated research in this area. The availability of messenger RNA from humans and other species and DNA has allowed the study of the receptor in artificial systems such as oocytes from frogs and in mammalian cells that do not express the receptor, such as COS or fibroblast cells. Receptors can also be mutated by molecular techniques to simulate pathologic states; the receptor function in these artificial systems can then be studied. By using these and related techniques, much has been learned about the synthesis, composition, and biologic function and mechanisms that underlie the physiologic and pharmacologic responses in AChRs.[51-53] Three isoforms of postjunctional nicotinic AChRs exist: a junctional or mature receptor, an extrajunctional or immature (fetal) receptor, and the more recently described neuronal α7 nicotinic receptor (see section on "Biology of Prejunctional and Postjunctional Nicotinic Acetylcholine Receptors").[2,16,18] The differences between receptor subtypes, however, can be neglected in a general discussion of the role of receptors in neuromuscular transmission.

AChRs are synthesized in muscle cells and are anchored to the end-plate membrane by a special 43-kd protein known as *rapsyn*. This cytoplasmic protein is associated with the AChR in a 1:1 ratio.[16-19] The receptors, formed of five subunit proteins, are arranged like the staves of a barrel into a cylindrical receptor with a central pore for ion channeling (the key features are illustrated in Fig. 12.4). The receptor protein has a molecular mass of approximately 250,000 daltons. The mature receptor consists of α1-, β1-, δ-, and ε-subunits, and the fetal (immature, extrajunctional) receptor consists of α1-, β1-, δ-, and γ-subunits; there are two subunits of α and one each of the others. The neuronal α7 AChR consists of five α7-subunits.[16,18] Each of all receptor subunits consists of approximately 400 to 500 amino acids. The receptor-protein complex passes entirely through the membrane and protrudes beyond the extracellular surface of the membrane and into the cytoplasm. The binding site for acetylcholine is on each of the α1- or α7- subunits, is located on the extracellular component of the α-subunit protein, and these are the sites of competition between receptor agonists and antagonists. Agonists and antagonists are attracted to the binding site, and either may occupy the site, which is located near cysteine residues

Fig. 12.4 Schematic illustration depicts acetylcholine receptor *(AChR)* channels *(right)* and tracings of cell-patch records of receptor channel openings *(left)*. The mature or junctional receptor consists of two α1-subunits and one each of β1-, δ-, and ε-subunits. The immature, extrajunctional, or fetal form consists of two α1-subunits and one each of β1-, δ-, and γ-subunits. The latter is thus called the γ-subunit receptor. Recently, a neuronal receptor consisting of five α7-subunits has been described in muscle. All the subunits are arranged around the central cation channel. The immature isoform containing the γ-subunit has long open times and low-amplitude channel currents. The mature isoform containing the ε-subunit has shorter open times and high-amplitude channel currents during depolarization. Substitution of the ε-subunit for the γ-subunit gives rise to the fast-gated, high-conductance channel type. As expected, application of acetylcholine to the α7 AChR also results in a fast, rapidly decaying inward current. All these depolarizing events are insensitive to treatment with muscarinic acetylcholine receptor antagonist, atropine, but sensitive to treatment with α-bungarotoxin or muscle relaxants, which block the flow of current. The affinity of the muscle relaxants to each of the three isoforms may be different, α7 AChR being the least sensitive to block.

(unique to the α-chain) at amino acid positions 192 to 193 of the α-subunit.[16-18] Radiolabeled α-bungarotoxin from the cobra, used to quantitate or fluorescent stain the receptor, binds to heptapeptide region 185 to 199 of the α-subunit.[54] Motor neuron-derived neuregulin-1β (NRβ-1), originally described as AChR-inducing activity (ARIA), induces AChR gene transcription in subsynaptic myonuclei by activating ErbB receptors.[16-19]

SYNTHESIS AND STABILIZATION OF POSTJUNCTIONAL RECEPTORS

Muscle tissue is formed from the mesoderm and initially appears as myoblasts. Myoblasts fuse to produce myotubes, which therefore have multiple nuclei. As the myotubes mature, the sarcomere, which is the contractile element of the muscle consisting of actin and myosin, develops.[55] The protein β-integrin seems to be essential for myoblast fusion and sarcomere assembly.[55] Shortly afterward, motor nerve axons grow into the developing muscle, and these axons bring in nerve-derived signals (i.e., growth factors), including agrin and neuregulins (NRβ-1 and NRβ-2), which are key to the maturation of myotubes to muscle.[19] Agrin is a protein from the nerve that stimulates postsynaptic differentiation by activating muscle-specific tyrosine kinase (MuSK), a tyrosine kinase expressed selectively in muscle. With signaling from agrin, the AChRs, which have been scattered throughout the muscle membrane, cluster at the area immediately beneath the nerve. Agrin, together with neuregulins and other growth factors, induce the clustering of other critical muscle-derived proteins, including MuSK, rapsyn, and ErbB proteins, all of which are necessary for maturation and stabilization of AChRs at the junction. In addition to the effects on postsynaptic differentiation, agrin and MuSK display effects on presynaptic differentiation as well. Agrin and MuSK induce retrograde signals that instruct axons to undergo neuron outgrowth and terminal differentiation.[19] Current understanding of presynaptic development of the neuromuscular junction, however, is significantly less advanced than the understanding of postsynaptic development. Just before and shortly after birth, the immature, γ-subunit-containing AChRs are replaced by the mature, ε-subunit-containing receptors. Although the mechanism of this change is unclear, a neuregulin, NRβ-1, also called *ARIA*, that binds to one of the ErbB receptors seems to play a role.[19,56]

BASIC ELECTROPHYSIOLOGY OF NEUROTRANSMISSION

Fig. 12.5 illustrates the results of the classic depolarizing action of acetylcholine on end-plate receptors. Normally, the pore of the channel is closed by approximation of the cylinders (i.e., subunits). When an agonist occupies both α-subunit sites, the protein molecule undergoes a conformational change with a twisting movement along the central axis of the receptor that results in the opening of the central channel through which ions can flow along a concentration gradient. When the central channel is open, sodium and calcium flow from the outside of the cell to the inside and potassium flows from the inside to the outside. The channel in the tube is large enough to accommodate many cations and electrically neutral molecules, but it excludes anions (e.g., chloride). The current transported by the ions depolarizes the adjacent membrane. The net current is depolarizing and creates the end-plate potential that stimulates the muscle to contract. In this instance, downward-going (i.e., depolarizing) current can be recorded by

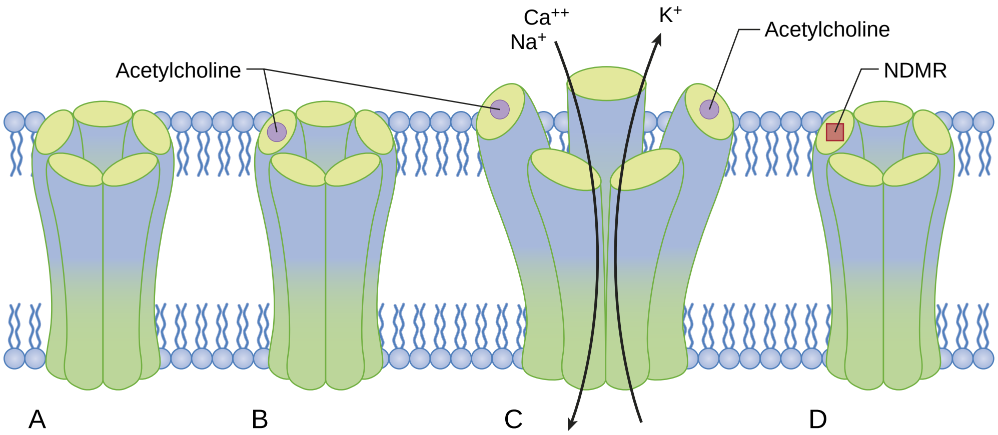

Fig. 12.5 Actions of acetylcholine or non-depolarizing muscle relaxant (NDMR) on end-plate receptors. (A) The ion channel is inactive and does not open in the absence of acetylcholine. (B) Although one acetylcholine molecule *(filled circle)* is binding to one of two binding sites, the central channel does not open. (C), When acetylcholine simultaneously binds to the recognition sites of both α-subunits *(filled circles)*, a conformation change is triggered that opens the channel and allows the cations to flow across the membrane. (D) Action of antagonists such as an NDMR *(filled square)*. Acetylcholine is in competition with NDMR for the receptor's recognition site but may also react with acetylcholinesterase. Inhibiting the acetylcholinesterase enzyme increases the lifetime of acetylcholine and the probability that it will react with a receptor. When one of the two binding (recognition) sites is occupied by an NDMR, the receptor will not open, even if the other binding site is occupied by acetylcholine. *Ca^{2++}*, Calcium ion; *K^+*, potassium ion; *Na^+*, sodium ion.

the patch-clamp electrophysiologic technique previously described (see Fig. 12.4).

The pulse stops when the channel closes by a reversed mechanical conformation (see earlier discussion), which is typically initiated when one or both agonist molecules detach from the receptor. In the activated, open state, the current that passes through each open channel is minuscule, only a few picoamperes (approximately 10^4 ions/ms). However, each burst of acetylcholine from the nerve normally opens approximately 500,000 channels simultaneously, and the total current is more than adequate to produce depolarization of the end plate and contraction of muscle. Opening of a channel causes conversion of chemical signals from a nerve to the flow of current on the muscle disease to cause end-plate potentials, thereby leading to muscle contraction. The end-plate potential has been viewed as a graded event that may be reduced in magnitude or extended in time by drugs, but, in reality, the end-plate potential is the summation of many all-or-nothing events simultaneously occurring at myriad ion channels. It is these tiny events that are affected by drugs.

Receptors that do not have two molecules of agonist (e.g., acetylcholine) bound remain closed. Both α-subunits must be simultaneously occupied by agonist; if only one of them is occupied, then the channel remains closed (see Fig. 12.5). This is the basis for preventing depolarization by antagonists. NDMRs act by binding to either or both α-subunits and thus preventing acetylcholine from binding and opening the channel. This interaction between agonists and antagonists is competitive, and the outcome—transmission or block—depends on the relative concentrations and binding characteristics of the drugs involved (see section on "Drug Effects on Postjunctional Receptors").

Individual channels are also capable of a wide variety of conformational states.[17,57] They may stay open or remain closed and thereby affect total current flow across the membrane, but they can do more. They may open for a longer or shorter time than normal, open or close more gradually than usual, open briefly and repeatedly (i.e., flickering), or pass fewer or more ions per opening than they usually do. Their function is also influenced by drugs, changes in fluidity of the membrane, temperature, electrolyte balance in the milieu, and other physical and chemical factors.[38,39] Receptor channels are dynamic structures that are capable of a wide variety of interactions with drugs and of entering a wide variety of current-passing states. All these influences on channel activity are ultimately reflected in the strength or weakness of neuromuscular transmission and contraction of a muscle.

Drug Effects on Postjunctional Receptors

CLASSIC ACTIONS OF NONDEPOLARIZING MUSCLE RELAXANTS

Neurotransmission occurs when acetylcholine released by the nerve action potential binds to nicotinic AChRs. All NDMRs impair or block neurotransmission by competitively preventing the binding of acetylcholine to the muscle AChR. The final outcome—block or transmission—depends on the relative concentrations of the chemicals and their comparative affinities for the receptor. Fig. 12.5 shows a system exposed to acetylcholine and the nondepolarizing neuromuscular blocking compound. One receptor has attracted two acetylcholine molecules and has opened its channel, where current will flow to depolarize that segment of membrane. Another has attracted one molecule of NDMR; its channel will not open, and no current will flow, even if one acetylcholine molecule binds to the other site. The third receptor has acetylcholine on one α-subunit and nothing on the other. What will happen depends on which of the molecules binds. If acetylcholine binds, then the channel will open and the membrane will be depolarized; if a NDMR binds, then the channel will remain closed and the membrane will not be depolarized. At other times, one or two molecules of NDMR may attach to the receptor, in which case the receptor is not available to agonists; no current flow is recorded. In the presence of moderate concentrations of NDMR, the amount of current flowing through the entire end plate at any instant is reduced from normal, which results in a smaller end-plate potential and, if carried far enough, a block in neurotransmission or the production of neuromuscular paralysis.

Normally, acetylcholinesterase destroys acetylcholine and removes it from competition for a receptor; therefore, an NDMR has a better chance of inhibiting transmission. If, however, an inhibitor of acetylcholinesterase such as neostigmine is added, then the cholinesterase cannot destroy acetylcholine. The concentration of agonist in the cleft remains high, and this high concentration shifts the competition between acetylcholine and a NDMR in favor of the former, thereby improving the chance of two acetylcholine molecules binding to a receptor even though NDMR is still in the environment. This mechanism causes the cholinesterase inhibitors to overcome the neuromuscular paralysis produced by NDMRs. The channel opens only when acetylcholine attaches to both recognition sites. A single molecule of antagonist, however, is adequate to prevent depolarization of that receptor. This modifies the competition by strongly biasing it in favor of the antagonist (relaxant). Mathematically, if the concentration of a NDMR is doubled, then the concentration of acetylcholine must be increased fourfold if acetylcholine is to remain competitive. Paralysis produced by high concentrations of muscle relaxants (antagonist) is more difficult to reverse with cholinesterase inhibitors than that produced by low concentrations. After large doses of NDMRs, cholinesterase inhibitors may be ineffective until the concentration of relaxant in the perijunctional area decreases to a lower level by the redistribution or elimination of the drug. This is the molecular basis for the recommendation to not administer anticholinesterases too early (i.e., at a deep block). In contrast to reversal with a cholinesterase inhibitor, cyclodextrin encapsulation takes place at any concentration of a steroid-based compound, such as vecuronium or rocuronium, and reversal by this novel mechanism can therefore be achieved at any level of neuromuscular block provided the amount of cyclodextrin (sugammadex) is large enough.

CLASSIC ACTIONS OF DEPOLARIZING MUSCLE RELAXANTS

Depolarizing relaxants (e.g., succinylcholine, decamethonium) initially simulate the effect of acetylcholine and can be considered agonists, despite the fact that they block neurotransmission after the initial stimulation. Structurally, succinylcholine is very similar to the natural ligand acetylcholine and consists of two molecules of acetylcholine bound together through their backbones. It is thus not surprising that succinylcholine can mimic the effects of acetylcholine.

Succinylcholine or decamethonium can bind to the receptor, open the channel, pass current, and depolarize the end plate. These agonists, similar to acetylcholine, attach only briefly; each opening of a channel is very short in duration—1 ms or less. The response to acetylcholine, however, is over in milliseconds because of its rapid degradation by acetylcholinesterase, and the end plate resets to its resting state long before another nerve impulse arrives. In contrast, the depolarizing relaxants characteristically have a biphasic action on muscle—an initial contraction, followed by relaxation lasting from minutes to hours. Because they are not susceptible to hydrolysis by acetylcholinesterase, the depolarizing relaxants are not eliminated from the junctional cleft until after they are eliminated from plasma. The time required to clear the drug from the body is the principal determinant of how long the drug effect lasts. Whole-body clearance of the relaxant is very slow in comparison to acetylcholine, particularly when plasma (pseudo) cholinesterase is abnormal. Because the relaxant molecules are not quickly cleared from the cleft, compared with acetylcholine, they repeatedly react with receptors even with normal levels of plasma cholinesterase, almost immediately attaching to a receptor after separating from another, thereby repeatedly depolarizing the end plate and opening channels. For details on the effect of succinylcholine in patients with cholinesterase deficiency, also see Chapter 27.

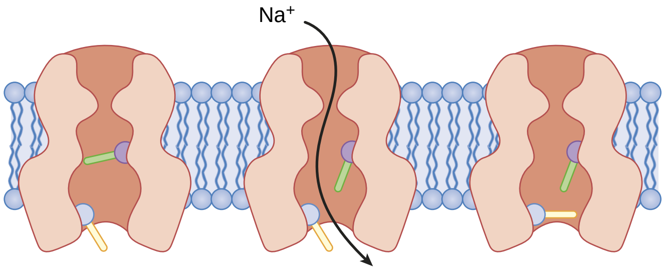

Fig. 12.6 Illustration of a sodium (Na^+) channel. The bars represent parts of the molecule that act as gates. The upper bar is voltage dependent; the lower bar is time dependent. The left side of the drawing represents the resting state. Once activated by a change in voltage, the molecule and its gates progress as illustrated *(left to right)*. See text for details.

The quick shift from excitation of muscle contraction to block of transmission by depolarizing relaxants occurs because the end plate is continuously depolarized. This comes about as a result of the juxtaposition of the edge of the end plate with a different kind of ion channel, the sodium channel that does not respond to chemicals but opens when exposed to a transmembrane voltage change. Just as the AChR, the sodium channel is also a cylindrical transmembrane protein through which sodium ions can flow. Two parts of its structure act as gates that allow or stop the flow of sodium ions.[58] Both gates must be open if sodium is to flow through the channel; closing of either cuts off the flow. Because these two gates act sequentially, a sodium channel has three functional conformational states and can progressively move from one state to another (Fig. 12.6). This whole process is short lived when depolarization occurs with acetylcholine.[58] The initial response of a depolarizing muscle relaxant resembles that of acetylcholine, but because the muscle relaxant is not rapidly hydrolyzed, depolarization of the end plate is not brief.

Depolarization of the end plate by the depolarizing relaxant initially causes the voltage gate in adjacent sodium channels to open, thereby producing a wave of depolarization that sweeps along the muscle and generates a muscle contraction. Shortly after the voltage-dependent gate opens, the time-dependent inactivation gate closes. Because the relaxant is not removed from the cleft, the end plate continues to be depolarized. Because the sodium channels immediately adjacent to the end plate are influenced by depolarization of the end plate, their voltage-dependent gates stay open and their inactivation gates stay closed. Since sodium cannot flow through a channel that has a closed inactivation gate, the perijunctional muscle membrane does not depolarize. When the flow of ions through sodium channels in the perijunctional zone stops because of a closure of the inactivation gates, the channels downstream (beyond the perijunctional zone) are freed of depolarizing influence. In effect, the perijunctional zone becomes a buffer that shields the rest of the muscle from events at the end plate. Consequently, the muscle membrane is separated into three zones: (1) the end plate, which is depolarized by succinylcholine; (2) the perijunctional muscle membrane, in which the sodium channels are frozen in an inactivated state; and (3) the rest of the muscle membrane, in which the sodium channels are in the resting state. Because a burst of acetylcholine from the nerve cannot overcome the inactivated sodium channels in the perijunctional zone, neuromuscular transmission is blocked. This phenomenon is also called *accommodation*. During accommodation, when the synapse is inexcitable through the nerve (transmitter), direct electrical stimulation of muscle causes muscle contraction because the sodium channels beyond the junctional area are in the resting excitable state.

The extraocular muscles are tonic muscles, which are multiply innervated and chemically excitable along most of their surfaces.[20-23] Despite their innervated state, the ocular muscles express both mature and immature receptors.[20,22] Accommodation does not occur, and these muscles can undergo a sustained contracture in the presence of succinylcholine. The tension that develops forces the eye against the orbit and accounts for part of the increase in intraocular pressure produced by depolarizing relaxants. The extraocular muscles contain a special type of receptor that does not become desensitized (see later discussion) during the continued presence of acetylcholine or other agonists.[21,23] A single dose of succinylcholine can cause contracture lasting several minutes.[23] Whether it is the immature γ-subunit AChR or the α7 AChR subunit that plays a role in this resistance to desensitization in the ocular muscles is unknown.

NONCLASSIC AND NONCOMPETITIVE ACTIONS OF NEUROMUSCULAR DRUGS

Several drugs can interfere with the receptor, directly or through its lipid environment, and can change transmission (Box 12.1). These drugs react with the neuromuscular receptor to change its function and impair transmission, but they do not act through the acetylcholine binding site. These reactions cause drug-induced changes in the dynamics of the receptor; instead of sharply opening and closing, the modified channels are sluggish. They open more slowly and stay open longer, or they close slowly and in several steps, or both. These effects on channels cause corresponding changes in the flow of ions and distortions of the end-plate potential. The clinical effect depends on the molecular events. For example, procaine, ketamine, inhaled anesthetics, or other drugs that dissolve in the membrane lipid may change the opening or closing characteristics of the channel.[57,59] If the channel is prevented from opening, then transmission is weakened. If, however, the channel is prevented from or slowed in closing, then transmission may be enhanced. These drugs do not fit the classic model, and the impaired neuromuscular function is not antagonized by increasing perijunctional acetylcholine concentrations with cholinesterase inhibitors. Such drugs can be involved in two clinically important reactions: receptor desensitization and channel block. The former occurs in the receptor molecule, whereas the latter occurs in the ion channel.

BOX 12.1 **Drugs That Can Cause or Promote Desensitization of Muscle Nicotinic Receptors**

- Volatile anesthetics
  - Halothane
  - Sevoflurane
  - Isoflurane
- Antibiotics
  - Polymyxin B
- Cocaine
- Alcohols
  - Ethanol
  - Butanol
  - Propanol
  - Octanol
- Barbiturates
  - Thiopental
  - Pentobarbital
- Agonists
  - Acetylcholine
  - Decamethonium
  - Carbachol
  - Succinylcholine
- Acetylcholinesterase inhibitors
  - Neostigmine
  - Pyridostigmine
  - Di-isopropyl-fluorophosphate
  - Edrophonium
- Local anesthetics
  - Dibucaine
  - Lidocaine
  - Prilocaine
  - Etidocaine
- Phenothiazines
  - Chlorpromazine
  - Trifluoperazine
  - Prochlorperazine
- Phencyclidine
- Calcium channel blockers
  - Verapamil

DESENSITIZATION BLOCK

The AChR, as a result of its flexibility and the fluidity of the lipid around it, is capable of existing in a number of conformational states.[57-61] Because the resting receptor is free of agonist, its channel is closed. The second state exists when two molecules of agonist are bound to the α-subunit of the receptor and the receptor has undergone the conformational change that opens the channel and allows ions to flow. These reactions are the bases of normal neuromuscular transmission. Some receptors that bind to agonists, however, do not undergo the conformational change to open the channel. Receptors in these states are called desensitized (i.e., they are not sensitive to the channel-opening actions of agonists). They bind agonists with exceptional avidity, but the binding does not result in the opening of the channel. The mechanisms by which desensitization occurs are not known. The receptor macromolecule, 1000 times larger by weight than most drugs or gases, provides many places at which the smaller molecules may act. The interface between lipid and receptor protein provides additional potential sites of reaction. Several different conformations of the protein are known, and because acetylcholine cannot cause the ion channel to open in any of them, they all are included in the functional term *desensitization*. Desensitization is accompanied by phosphorylation of a tyrosine unit in the receptor protein.[61,62]

Although agonists (e.g., succinylcholine) induce desensitization, the receptors are in a constant state of transition between resting and desensitized states, regardless of whether agonists are present. Agonists do promote transition to a desensitized state or, because they bind very tightly to desensitized receptors, trap a receptor in a desensitized state. NDMRs also tightly bind to desensitized receptors and can trap molecules in these states. This action of NDMRs is not competitive with that of acetylcholine; it may be augmented by acetylcholine if the latter promotes the change to a desensitized state. Desensitization can lead to significant misinterpretation of data. Superficially, the preparation seems to be normal, but its responsiveness to agonists or antagonists is altered. One variety occurs very rapidly, within a few milliseconds after application of an agonist, which may explain the increased sensitivity to nondepolarizing relaxant after the prior administration of succinylcholine. Desensitization may also be a part of the phenomenon known as *phase II block* (see section on “Phase II Block”), which is caused by a prolonged administration of depolarizing relaxants. Phase II block is frequently referred to as a desensitization block, but it should not be because desensitization of receptors is only one of many phenomena that contribute to the process.

Many other drugs used by anesthetists also promote the shift of receptors from a normal state to a desensitized state.[58-60] These drugs, some of which are listed in Box 12.1, can weaken neuromuscular transmission by reducing the margin of safety that normally exists at the neuromuscular junction, or they can cause an apparent increase in the capacity of NDMRs to block transmission. These actions are independent of the classic effects, based on competitive inhibition of acetylcholine. The presence of desensitized receptors means that fewer receptor channels than usual are available to carry transmembrane current. The production of desensitized receptors decreases the efficacy of neuromuscular transmission. If many receptors are desensitized, then insufficient normal ones are left to depolarize the motor end plate, and neuromuscular transmission will not occur. Even if only some receptors are desensitized, neuromuscular transmission will be impaired, and the system will be more susceptible to block by conventional antagonists such as atracurium or rocuronium.

CHANNEL BLOCK

Local anesthetics and calcium entry blockers prevent the flow of sodium or calcium through their respective channels, thus explaining the term *channel-blocking drugs*. Similarly, block of the flow of ions can occur at the AChR with concentrations of drugs used clinically and may contribute to some of the phenomena and drug interactions observed at the receptor. Two major types, closed-channel and open-channel block, can occur.[60,63,64] In a closed-channel block, certain drugs can occupy the mouth of the channel and prevent ions from passing through the channel to depolarize the end plate. The process can take place even when the channel is not open. In an open-channel block, a drug molecule enters a channel that has been opened by reaction with acetylcholine but does not necessarily penetrate all the way through. Open-channel block is a use-dependent block, which means that molecules can enter the channel only when it is open. In open- and closed-channel blocks, the normal flow of ions through the receptor is impaired, thereby resulting in the prevention of depolarization of the end plate and a weakened or blocked neuromuscular transmission. However, because the action is not at the acetylcholine recognition site, it is not a competitive antagonism of acetylcholine and is not relieved by anticholinesterases that increase concentrations of acetylcholine. Increasing the concentration of acetylcholine may cause the channels to open more often and, consequently, become more susceptible to block by use-dependent compounds. Evidence suggests that neostigmine and related cholinesterase inhibitors can act as channel-blocking drugs.[17,63]

Channel block may account for the antibiotic-, cocaine-, quinidine-, piperocaine-, tricyclic antidepressant-, naltrexone-, naloxone-, and histrionicotoxin-induced alterations in neuromuscular function. Muscle relaxants, in contrast, can bind to the acetylcholine recognition site of the receptor and occupy the channel. Pancuronium preferentially binds to the recognition site. Gallamine (not used clinically anymore) seems to act equally at the two sites (channel-blocking and acetylcholine-blocking sites). (Gallamine was synthesized by Daniel Bovet, a Swiss-born Italian pharmacologist and received the Nobel Prize in Physiology or Medicine in 1957 for his work on cardiovascular and neuromuscular pharmacology.) Tubocurarine, the first NDMR used clinically, is in between; at small doses that clinically produce minimal blockage of transmission, the drug is essentially a pure antagonist at the recognition site; at larger doses, it also enters and blocks channels. Decamethonium and succinylcholine, as agonists, can open channels and, as slender molecules, also enter and block them. Decamethonium and some other long, thin molecules can penetrate all the way through the open channel and enter the cytoplasm of muscle cells. Whether prolonged administration of NDMRs, as used in an intensive care unit, can result in the NDMR occupation of the channel, and even entry of drug into the cytosol, is unknown.

PHASE II BLOCK

A phase II block is a complex phenomenon associated with a typical fade in muscle during continuous exposure to depolarizing drugs. This fade phenomenon is likely due to the interaction of depolarizing action of succinylcholine on distinct neuronal (prejunctional) AChRs; these prejunctional receptors are blocked by higher-than-usual concentrations of succinylcholine. This fade after succinylcholine is at least partly dependent on a presynaptic interaction with cholinergic transmission of importance for neurotransmitter mobilization and release. However, fade in muscle during repetitive nerve stimulation can also be attributable to postjunctional AChR block.[65]

Other factors may also be involved. The repeated opening of channels allows a continuous efflux of potassium and influx of sodium, and the resulting abnormal electrolyte balance distorts the function of the junctional membrane. Calcium entering the muscle through the opened channels can cause disruption of receptors and the sub-end-plate elements themselves. The activity of the sodium-potassium adenosine triphosphatase pump in the membrane increases with increasing intracellular sodium and, by pumping sodium out of the cell and potassium into it, works to restore the ionic balance and membrane potential toward normal. As long as the depolarizing drug is present, the receptor channels remain open and ion flux through them remains frequent.[66]

Factors influencing the development of a phase II block include the duration of exposure to the drug, the particular drug used and its concentration, and even the type of muscle (i.e., fast or slow twitch). Interactions with anesthetics and other agents also affect the process. All these drugs may also have prejunctional effects on the rate and amount of transmitter released and mobilized. With so many variables involved in the interference with neuromuscular transmission, a phase II block is a complex and ever-changing phenomenon. The reversal response of a phase II block produced by a depolarizing muscle relaxant to the administration of cholinesterase inhibitors is difficult to predict. It is therefore best that reversal by cholinesterase inhibitors not be attempted, although the response to tetanus or train-of-four stimulation resembles that produced by NDMRs.

Biology of Prejunctional and Postjunctional Nicotinic Acetylcholine Receptors

POSTJUNCTIONAL CONVENTIONAL ACETYLCHOLINE RECEPTORS IN MUSCLE VERSUS NEURONAL ACETYLCHOLINE RECEPTORS IN MUSCLE

Currently, three variants of postjunctional AChRs have been identified. The AChR isoform present in the innervated, adult neuromuscular junction is referred to as the adult, mature, or junctional receptor. Another AChR isoform, also described more than 4 decades ago, is expressed when activity in muscle is decreased, as observed in the fetus before innervation or after chemically- or physically-induced immobilization; after lower or upper motor neuron injury, burns, or sepsis; or after other events that cause increased muscle protein catabolism, including sepsis or generalized inflammation.[1-3] In contrast with the mature or junctional receptors, the other isoform is referred to as the immature, extrajunctional, or fetal form of AChR. Some evidence suggests that the immature isoform is not observed in the muscle protein catabolism and wasting that occur with malnutrition.[67] Qualitative differences in the mature isoform can occur as a result of gene mutations, which therefore alters the subunit protein structure. These qualitative changes in AChR can also cause abnormalities in neurotransmission (e.g., slow- or fast-channel syndrome)[27,47] and therefore the response to muscle relaxants.

At the molecular level, the mature and immature receptors consist of five subunits (see Fig. 12.4).[1-3] The mature junctional receptor is a pentamer of two $\alpha1$-subunits and one each of the $\beta1$-, δ-, and ε-subunits. The immature receptor consists of two $\alpha1$-subunits and one each of the $\beta1$-, δ-, and γ-subunits; that is, in the immature receptor, the γ-subunit is present instead of the ε-subunit. The γ- and ε-subunits differ very little from each other in amino acid homology, but the differences are great enough to affect the physiologic function and pharmacologic characteristics of the receptor and its ion channel. Junctional receptors are always confined to the end-plate region of the muscle membrane. The immature, or extrajunctional, receptor may be expressed anywhere on the muscle membrane, although their junctional expression seems minimal.[16] During development and in certain pathologic states, junctional and extrajunctional receptors can coexist in the perijunctional area of the muscle membrane (Fig. 12.7).

Quite in contrast to the conventional muscle AChRs consisting of $\alpha1$-, $\beta1$-, δ-, and ε/γ-subunits described earlier, receptors formed of $\alpha7$ AChR subunits have recently been found in skeletal muscle during immobilization, sepsis, and denervation.[68,69] Two recent studies have evidenced the increased expression of $\alpha7$ AChR subunits in muscle by western blotting, ligand binding or genetic techniques after sepsis, and burn injury or immobilization, during which no overt denervation occurs.[16,70] These $\alpha7$ AChR subunits are homomeric (i.e., formed of the same subunits) channels arranged as pentameres (see Fig. 12.4). Ligand (drug)-binding pockets are thought to be formed at negative and positive faces of the $\alpha7$-subunit assembly interphases. As expected, the endogenous agonist, acetylcholine, binds to $\alpha7$ AChR subunits, and each of the five subunits has the potential to bind acetylcholine or succinylcholine molecules.[18,69] Other agonists, including nicotine and choline, and antagonists, including muscle relaxants, cobra toxin, and α-bungarotoxin, also bind to the $\alpha7$ AChR.[18,69-72]

The $\alpha7$ AChRs in muscle display unusual functional and pharmacologic characteristics when compared with conventional muscle ($\alpha1$, $\beta1$, δ, ε/γ) AChRs or neuronal $\alpha7$ AChRs in the brain. Choline, a precursor and metabolite of acetylcholine (and succinylcholine), is a weak agonist of conventional muscle AChRs but is a full agonist of muscle $\alpha7$ AChRs; that is, concentrations of choline that do not open conventional AChR channels will open $\alpha7$ AChR channels.[69] Furthermore, no desensitization of the $\alpha7$ AChRs occurs even during the continued presence of choline,[69] thus allowing a greater chance for potassium to efflux (approximately 145 mEq/L) from within the cell to the extracellular space, including plasma (approximately 4.5 mEq/L), down its concentration gradient. The chemical

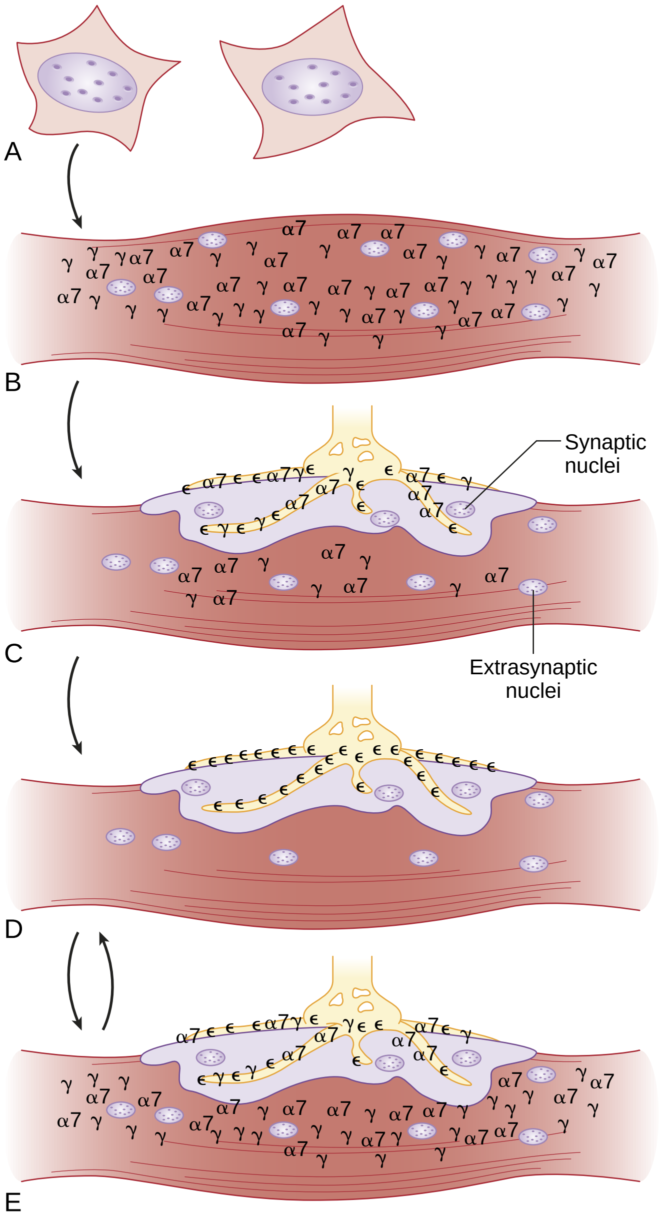

Fig. 12.7 Distribution of acetylcholine receptors in developing adult mature, denervated or immobilized muscle and in inflammation-induced catabolic muscle. (A and B) In the early fetal stage, mononucleated myoblasts, derived from the mesoderm, fuse with each other to form multinucleated myotubes. The γ-subunit-containing immature acetylcholine receptors (AChRs) and the neuronal α7-subunit AChRs are scattered throughout the muscle membrane before innervation. (C) As the nerve makes contact with muscle, clustering of the receptors occurs at the synapse and is associated with some loss of extrasynaptic receptors. (D) Maturation of the junction is said to occur when ε-subunit-containing receptors replace γ-subunit- and α7-subunit-containing AChRs at the neuromuscular junction. Even mature muscle is multinucleated, but it is devoid of extrasynaptic AChRs. (E) Denervation and some other pathologic states, even without anatomic denervation (e.g., burns, immobilization, chronic muscle relaxant therapy, stroke, sepsis), lead to the re-expression of the γ-subunit-containing AChRs mostly at the extrajunctional areas. The α7-subunit AChRs are expressed in the junctional areas and are also most likely in the extrajunctional areas. These receptor changes are potentially reversible if muscle immobilization, catabolism, and inflammation are restored to normal.

α-conotoxin GI from the snail specifically inhibits the conventional (mature and immature) AChRs in muscle but does not inhibit α7 AChRs. The important role of α7 AChRs in resistance to NDMRs is evidenced by the presence of immobilization-induced resistance in wild-type mice and the absence of resistance in α7 AChRs knockout mice.[73] The α7 AChRs expressed in neuronal tissue are also readily desensitized with choline, a feature that contrasts with muscle α7 AChRs, which do not desensitize with choline.[69] The α7 AChRs in muscle also have lower affinity for its antagonists, including pancuronium, rocuronium, atracurium, or α-bungarotoxin; higher concentrations of these drugs are therefore required to block agonist-induced depolarization in α7 AChRs in vitro or cause neuromuscular paralysis in vivo or ex vivo when α7 AChRs are upregulated.[69-72] In the conventional muscle AChRs, binding of even one of the α1-subunits by an antagonist results in inactivation of that receptor because acetylcholine needs both α1-subunits of the AChR for its activation. In α7 AChRs, however, even when three subunits are bound by an antagonist (e.g., muscle relaxant), two other subunits are still available for binding by agonist and cause depolarization. This feature may account for some of the resistance to muscle relaxants when α7 AChRs are expressed in muscle and other tissues in pathologic states.[69-73]

The clinical pharmacologic characteristics of the muscle α7 AChR have not yet been completely studied, but its basic composition also provides some insight into succinylcholine-related hyperkalemia. Chemical or physical denervation of muscle results in not only upregulation and qualitative (ε-subunit → γ-subunit) changes in AChRs, but it also results in upregulation of α7 AChRs in muscle. Succinylcholine, a synthetic analog of acetylcholine that consists of two molecules of acetylcholine joined together, is capable of depolarizing not only conventional AChRs but also α7 AChRs in muscle.[72] In addition, the metabolite of succinylcholine, choline, can depolarize α7 AChRs with little desensitization. The depolarizing effects of succinylcholine and choline on upregulated α7 AChRs can result in continued leakage of intracellular potassium and flooding of extracellular fluid, including plasma, thereby leading to hyperkalemia. Thus, differences in the subunit composition and increased numbers of the three isoforms junctionally and extrajunctionally expressed may account for aberrant responses to muscle relaxants clinically observed as resistant only to NDMRs and hyperkalemic response to succinylcholine.[2,72,73]

MAINTENANCE OF MATURE NEUROMUSCULAR JUNCTIONS

Quite unlike other cells, muscle cells are unusual in that they have many, usually hundreds, of nuclei per cell. Each nucleus has the genes to make all three isoform receptors. Multiple factors, including electrical activity, growth factor signaling (e.g., insulin, agrin, neuregulins), and the presence or absence of innervation, control the expression of the three types of receptor isoforms.[19,37] This control is most clearly observed in the developing embryo as the neuromuscular junction is formed. Before they are innervated, the muscle cells of a fetus synthesize only immature and α7 AChRs—hence the term *fetal isoform* for the former receptor. Synthesis is directed by nearly all of the nuclei in the cell, and the AChRs are expressed throughout the membrane of the muscle cell (see Fig. 12.7). As the fetus develops and the muscles become innervated, muscle cells begin to synthesize the mature isoform of receptors, which are exclusively inserted into the developing (future) endplate area.[14-19] The nerve releases several growth factors that influence the synthetic apparatus of the nearby nuclei. First, nerve-supplied factors induce the subsynaptic nuclei to increase synthesis of AChRs. Next, the nerve-induced electrical activity results in the repression of receptors in the extrajunctional area (see Fig. 12.7*B* and *C*). Nerve-derived growth factors, including agrin and ARIA/neuregulin, cause the receptors to cluster in the subsynaptic area and prompt the expression of the mature isoform.[19,37] Several lines of evidence indicate that clustering, expression, and stabilization of mature receptors are triggered by at least two growth factors: agrin, neuregulin/ARIA, and possibly calcitonin gene-related peptide.[56,74,75] Neuregulin and agrin are also released from muscle, but muscle-derived agrin is not as important in clustering and maturation of the receptor. ARIA is made in the nerve and plays a role in the maturation of vesicular arrangement and conversion of the γ-to-ε switch.[75] All of these growth factors interact with distinct membrane and cytosolic receptor proteins to cause phosphorylation and activation of nuclear (gene) transcriptional systems. Agrin signals through MuSK and neuregulins through ErbB receptors (Fig. 12.8). These receptors control qualitative and quantitative changes at the junction. Once begun, the process is very stable, and nuclei in the junctional area continue to express mature receptors. In certain pathologic state–induced insulin resistance, a concomitant proliferation of AChRs seems to occur beyond the junctional area. Conditions in which this form of insulin resistance (i.e., decreased growth factor signaling) has been observed include immobilization, burn injury, sepsis, and denervation[75-78]; in these conditions, not only does upregulation of total AChRs occur, but de novo upregulation of the immature and α7 AChR isoforms are also observed (see Fig. 12.7*D*).[1-3] This upregulation may be related to the lack of growth factor effects of agrin and possibly neuregulin, which signal via some of the same downstream signaling proteins as insulin (e.g., phosphoinositide 3-kinase).[56,76-79] Therefore, agrin and neuregulin signaling may be important for the suppression of α7 AChRs and immature AChRs in the normal neuromuscular junction.

Before innervation, as in the fetus, AChRs are present throughout the muscle membrane. After innervation, AChRs become more and more concentrated at the postsynaptic membrane and are virtually absent in the extrasynaptic area at birth. The innervation process progresses somewhat slowly during fetal life and matures during infancy and early childhood.[14-19] With time, the immature receptors diminish in concentration and disappear from the peripheral part of the muscle. In the active, adult, and normal innervated muscle, just the nuclei under and very near the end plate direct the synthesis of the receptor; only the genes for expressing mature receptors are active. Nuclei beyond the junctional area are not active, and therefore no receptors are expressed anywhere in the muscle cells beyond the perijunctional area. Conversion of all the γ-subunit- to ε-subunit-containing AChRs in the perijunctional area continues to take place after birth. In the rodent, conversion takes approximately 2 weeks.[14-19] In humans, this process takes longer. The timeframe for the disappearance of α7 AChRs in the fetus or newborn is also unknown. Proteins implicated in the linking of mature receptors to the cytoskeleton include integrin, syntrophin, utrophin, α- and β-dystroglycan, and rapsyn, just to name a few.[14-19]

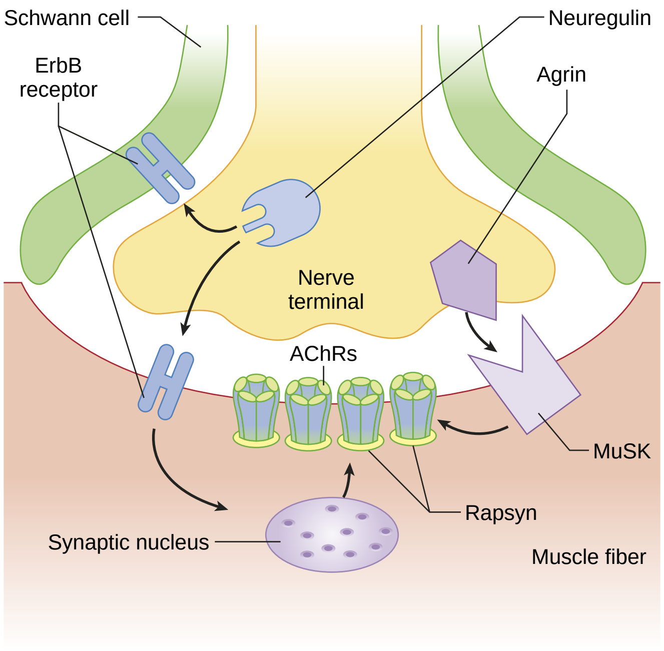

Fig. 12.8 Diagram of agrin- and acetylcholine receptor-inducing activity (ARIA)/neuregulin-dependent events during maturation of the neuromuscular junction. After the establishment of a nerve on the muscle, growth factors, including agrin and neuregulins, are released. Neuregulin signaling is essential for Schwann cell survival, and Schwann cells are essential for axonal maintenance. Agrin interacting with its receptor muscle-specific tyrosine kinase *(MuSK)* enhances the clustering of synaptic proteins, including acetylcholine receptors *(AChRs)*, rapsyn, and ErbB receptors. ARIA/neuregulin is the best candidate for the involvement in the conversion of γ-subunit-containing immature receptor to ε-subunit-containing mature (innervated) receptor, which is synapse specific and therefore not inserted in the extrajunctional area.

RE-EXPRESSION OF IMMATURE (FETAL) γ-SUBUNIT AND α7-SUBUNIT ACETYLCHOLINE RECEPTORS IN ADULT LIFE

The extrajunctional immature receptors can reappear soon after upper and lower motor denervation and in certain pathologic states (e.g., burns, sepsis, immobilization, chronic muscle relaxant therapy or botulism, loss of muscle electrical activity). Stimulation of a denervated muscle with an external electrical stimulus can prevent the appearance of immature receptors. It has been suggested that the calcium that enters the muscle during activity is important in the suppression process.[16,17] In the pathologic states previously enumerated, if the process is severe and prolonged, then extrajunctional receptors are inserted all over the surface of the muscle, including the perijunctional area (see Fig. 12.7*D*). The junctional nuclei also continue to make mature receptors. The synthesis of immature receptors is initiated within hours of inactivity, but it takes several

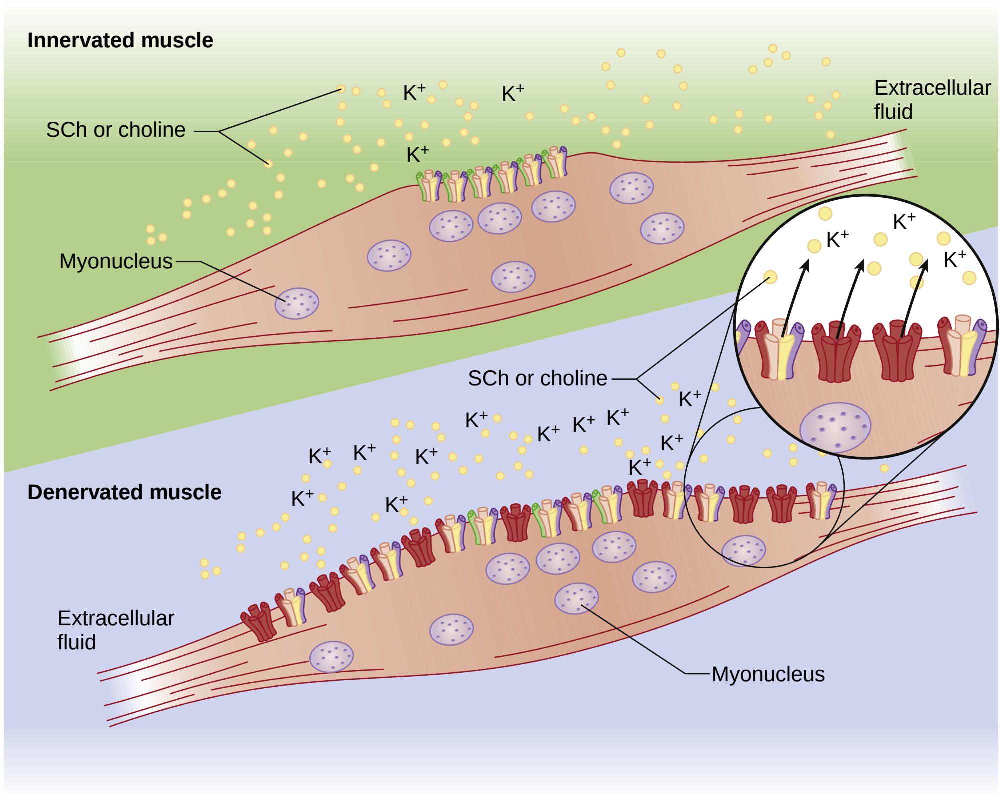

Fig. 12.9 Schematic of the succinylcholine (SCh)-induced potassium (K^+) release in an innervated *(top)* and denervated muscle *(bottom)*. In the innervated muscle, the systemically administered SCh reaches all the muscle membrane but depolarizes only the junctional (α1, β1, δ/ε) receptors because acetylcholine receptors (AChRs) are located only in this area. With denervation, the muscle nuclei express not only extrajunctional (α1, β1, δ/γ) AChRs but also α7-nicotinic AChRs throughout the muscle membrane. Systemic SCh, in contrast to acetylcholine released locally, can depolarize all the upregulated AChRs, which leads to massive efflux of intracellular K^+ into the circulation, resulting in hyperkalemia. The metabolite of SCh, choline, and possibly succinylmonocholine, can maintain this depolarization via α7-nicotinic AChRs, enhancing the K^+ release and maintaining the hyperkalemia. (From Martyn JAJ, Richtsfeld M. Succinylcholine-induced hyperkalemia in acquired pathologic states: etiologic factors and molecular mechanisms. *Anesthesiology*. 2006;104:158–169, 2006.)

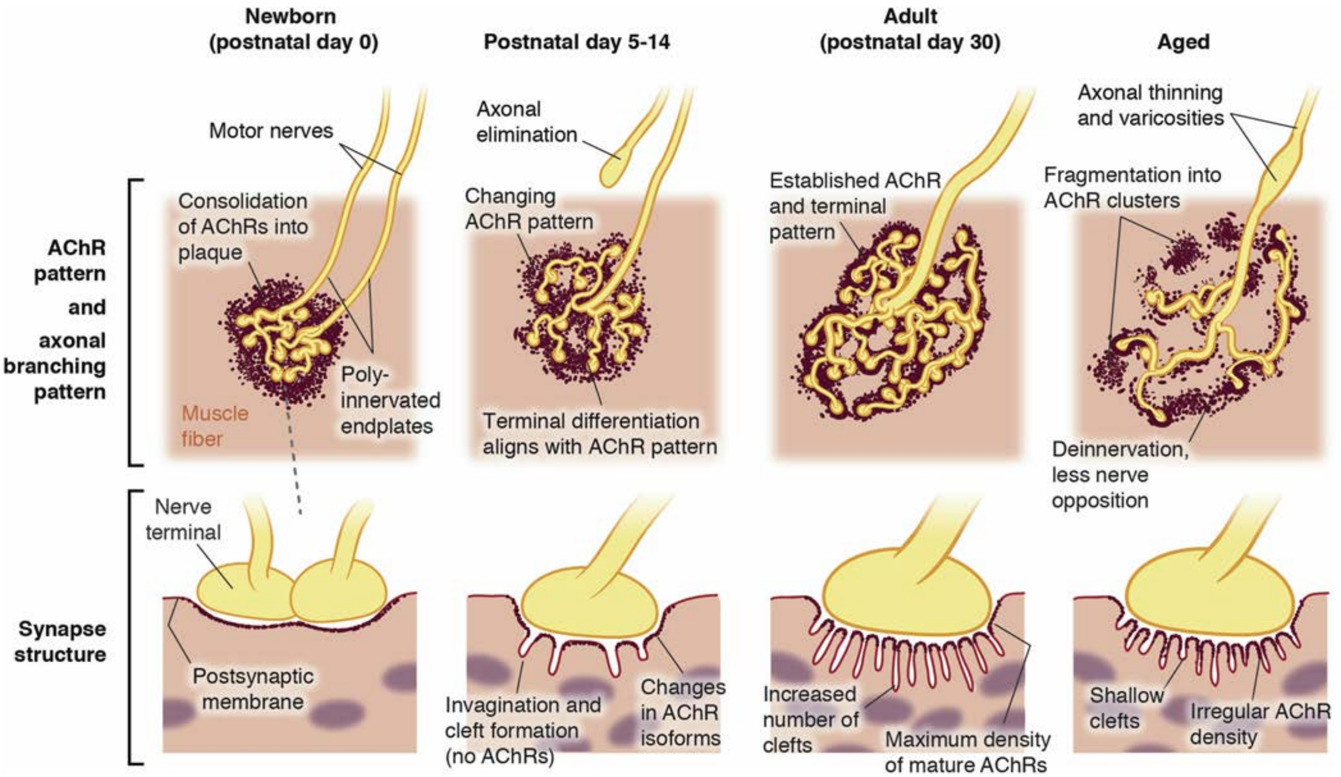
days for the whole muscle membrane to be fully covered with receptors. This upregulation of receptors has implications for the use of depolarizing and possibly NDMRs. The changes in α7 AChRs parallel the expression of immature receptors, although this has not been well studied.

The changes in subunit composition (γ vs. ε) in the receptor confer certain changes in electrophysiologic (functional), pharmacologic, and metabolic characteristics.[16-18] Mature receptors are metabolically stable, with a half-life approximating 2 weeks, whereas immature receptors have a metabolic half-life of less than 24 hours. Immature receptors have a smaller single-channel conductance and a twofold to tenfold longer mean channel open time than do mature receptors (see Fig. 12.4). The changes in subunit composition may also alter the sensitivity or affinity, or both, of the receptor for specific ligands. Depolarizing or agonist drugs such as succinylcholine and acetylcholine more easily depolarize immature receptors, thereby resulting in cation fluxes; doses one tenth to one hundredth of those needed for mature receptors can effect depolarization.[2] The potency of NDMRs is also reduced, as demonstrated by the resistance to their neuromuscular effects documented in patients with burns, denervation, sepsis, and immobilization.[1,3] In light of recent research, however, it seems that the resistance to nondepolarizers is more likely due to the junctional area expression of the α7 AChRs, which has a decreased affinity to NDMRs.[16,69-73] Some NDMRs may also cause a partial agonist response in immature receptors, thus explaining the decreased potency in conditions in which upregulation of AChRs occurs.[8] The upregulation of immature AChRs in the perijunctional and extrajunctional areas may have a buffering effect for diffusion of relaxants, contributing to resistance to NDMRs.[80]

The altered sensitivity to muscle relaxants may occur in only certain parts of the body or certain muscles if only some muscles are affected by the diminution in nerve activity (e.g., after a stroke). Sensitivity to relaxants can begin to change beyond 72 hours after an injury or hospitalization. The most serious side effect with the use of succinylcholine in the presence of upregulated AChRs in one or more muscles is hyperkalemia.[1-3] In these subjects, the receptors can be scattered over a large surface of the muscle. The AChR channels opened by the agonist (succinylcholine) allow potassium to escape from the muscle and enter the blood (Fig. 12.9).[2,3] If a large part of the muscle surface consists of upregulated (immature) receptor channels, each of which stays open for a longer time, then the amount of potassium that moves from muscle to blood can be considerable. The resulting hyperkalemia can cause dangerous disturbances in cardiac rhythm, including ventricular fibrillation. Moreover, hyperkalemia probably cannot be prevented by prior administration of NDMRs because large doses required to



Newborn (postnatal day 0)
Postnatal day 5-14
Adult (postnatal day 30)
Aged
AChR pattern and axonal branching pattern
Motor nerves
Consolidation of AChRs into plaque
Poly-innervated endplates
Muscle fiber
Axonal elimination
Changing AChR pattern
Terminal differentiation aligns with AChR pattern
Established AChR and terminal pattern
Axonal thinning and varicosities
Fragmentation into AChR clusters
Deinnervation, less nerve opposition
Synapse structure
Nerve terminal
Postsynaptic membrane
Invagination and cleft formation (no AChRs)
Changes in AChR isoforms
Increased number of clefts
Maximum density of mature AChRs
Shallow clefts
Irregular AChR density

Fig. 12.10 Maturation of the postsynaptic apparatus. *Postnatal day 0 (Newborn)*: At the time of birth, the aggregates of acetylcholine receptors (AChRs) have consolidated to form an oval-like plaque with irregular borders. At this point, each junction may have more than one nerve terminal innervating it. *Postnatal day 5 to 14*: Approximately 5 to 14 days after birth, the postsynaptic membrane invaginates to form a gutter and small perforations develop on the plaque. These perforations reflect gaps due to the synaptic clefts (which do not have AChRs). During this time, the immature γ-subunit-containing AChRs are completely replaced by mature AChRs containing ε-subunit. The invaginations or clefts increase in numbers, resulting in more perforations in the synaptic AChRs giving it an almost pretzel-shaped junction. The perforations, as indicated, correspond to the synaptic clefts or folds. *Postnatal day 30*: The neuromuscular junction is completely developed (mature) at 30 days after birth with a larger pretzel-shaped appearance. The AChRs have maximal density. A distinct set of postsynaptic proteins and signaling molecules are selectively transcribed in the subsynaptic area, providing integrity to the neuromuscular junction and efficient neurotransmission. *Aged NMJ*: Examination of NMJ in the aged mice and humans reveal marked morphological changes. Some of the synapses undergo partial degeneration and synaptic staining becomes fainter. The synaptic folds are smaller in depth. The nerve terminals become thinner and appear swollen or bulbous with less apposition with the synapse. The Schwann cells seems to invade into the NMJ more (not shown). *NMJ,* neuromuscular junction.

block the AChRs, in and of itself, will cause paralysis, obviating the need for succinylcholine.[3] Larger-than-normal doses of NDMRs may attenuate the increase in blood potassium concentrations but cannot completely prevent it. In other words, no hyperkalemic response to succinylcholine has been seen earlier than 4 days after perturbations described previously.[50] However, hyperkalemia and cardiac arrest can occur after the administration of succinylcholine, even in the absence of denervation states. These effects are observed in certain congenital muscle dystrophies in which the muscle membrane is prone to damage by the depolarization produced by succinylcholine, resulting in potassium release via the membrane damage.[81]

PREJUNCTIONAL ACETYLCHOLINE RECEPTORS

Nicotinic AChRs exist in a variety of forms apart from that observed in muscle.[16,18] The classic muscle-type nicotinic AChR is postsynaptically present, whereas neuronal subtype receptors may be presynaptically and postsynaptically present. The neuronal subtype nicotinic AChRs expressed prejunctionally are usually heteromeric and built up by *only* α- and β-subunits. This family of nicotinic AChRs is widely expressed in the peripheral and central nervous systems, on autonomous nerves and ganglia on oxygen-sensing cells within the carotid bodies. There are also α7 AChRs in immune-competent cells, such as macrophages, microglia lymphocytes and granulocytes, and fibroblasts and chondrocytes.[16,18] Diverse genes encode the heterogeneous AChRs, and the ion channel is formed of multiple subunits (multimers). Seventeen AChR genes have been cloned from vertebrates. They include various combinations of α-subunits (α1 through α10) and β-subunits (β1 through β4) and one each of γ-, δ-, and ε-subunits. The γ-, δ-, and ε-subunits are found only in muscle.[16-18]

Prejunctional- or nerve terminal-associated cholinergic receptors have been demonstrated by morphologic pharmacologic and by molecular biologic techniques, but their form and functions are not as completely understood as those in the postjunctional area. Many drugs with an abundance of potential targets for drug action can affect the capacity of the nerve terminal to carry out its functions. The trophic function to maintain nerve-muscle contact involves the release and replenishment of acetylcholine together with other trophic factors that require signaling through many receptors, of which the prejunctional nicotinic AChR is just one. Succinylcholine produces fasciculations that can be prevented by NDMRs. Because a fasciculation is, by definition, the simultaneous contraction of the multitude of muscle cells in a single motor unit and because only the nerve can synchronize all the muscles in its motor unit, it became apparent that succinylcholine must also act on nerve endings. Because NDMRs prevent fasciculation, it was concluded that they acted on the same prejunctional receptor. Very small doses of cholinergic agonists (e.g., succinylcholine) and antagonists (e.g., NDMRs) affect nicotinic receptors on the nerve ending; the former by depolarizing the ending and sometimes inducing repetitive firing of the nerve and the latter by preventing the action of agonists.[5]

By the use of specific monoclonal antibodies, the presence of nicotinic α3-subunits has been demonstrated in the nerve terminal.[82] Another clue to the differences between prejunctional and postjunctional AChRs was the finding that some drugs (e.g., dihydro-β-erythroidine) bind only to prejunctional AChRs, whereas other drugs (e.g., α-bungarotoxin) bind only to postjunctional receptors.[65] Additional clues were found in the many demonstrations of quantitative differences in the reaction of prejunctional and postjunctional nicotinic receptors to other cholinergic agonists and antagonists.[65,82-84] For instance, it was known that tubocurarine, the first NDMR introduced to clinical practice in 1942 (not used in US or Europe), binds with lower affinity to the recognition sites of ganglionic nicotinic cholinoceptors and is not a competitive antagonist of acetylcholine at this site. Decamethonium (i.e., a depolarizing muscle relaxant no longer clinically used) is a selective inhibitor of the muscle receptor, and hexamethonium is a selective inhibitor of nicotinic receptors in the autonomic ganglia.[80-85] Instead, tubocurarine and hexamethonium can block the opened channels of these receptors and owe their ability to block ganglionic transmission to this property. The functional characteristics of prejunctional receptor channels may also be different. For example, the depolarization of motor nerve endings initiated by the administration of acetylcholine can be prevented by tetrodotoxin, a specific blocker of sodium flux with no effect on the end plate.

Specific information on the molecular organization of neuronal nicotinic receptors on the motor neuron terminal is still lacking. Some of the subunit composition is similar, but other subunits do not resemble those of the postjunctional receptor. Of the 16 different nicotinic AChR gene products identified, only 12 (α2 to α10 and β2 to β4) are thought to contribute nicotinic receptors expressed on neurons. Most strikingly, nervous tissue does not express γ-, δ-, or ε-receptor subunits; it contains genes only for the α- and β-subunits. The α- and β-subunit genes in nerve and muscle are not exactly the same; they are variants. To emphasize the distinction between neural and muscle nicotinic receptors, the former are sometimes designated *Nn* and the latter *Nm*. With so many different subunits available, possible combinations are many, and it is not known which combinations are found in motor nerves. Their physiologic roles have also not been completely characterized. Expression of neuronal nicotinic AChRs in *in vitro* systems has confirmed that muscle relaxants and their metabolites can bind to some of these neuronal AChRs.[53,83-85]

The nicotinic receptor on the junctional surface of the nerve (nerve terminal) senses transmitter in the cleft and, by means of a positive-feedback system, causes the release of more transmitter. In other parts of the nervous system, this positive feedback is complemented by a negative-feedback system that senses when the concentration of transmitter in the synaptic cleft has appropriately increased and shuts down the release system. It is believed that tetanic fade and train-of-four fade during neuromuscular block with NDMRs arise from presynaptic cholinergic autoreceptors at the motor nerved ending.[5,52]

The neuronal AChR subtype that is critically involved in acetylcholine release and subsequent fade phenomenon (as observed in tetanic or train-of-four stimulus patterns) has been identified as the α3β2-subtype nicotinic AChR.[10,84] When this prejunctional receptor is specifically blocked by a nondepolarizing relaxant such as tubocurarine, a reduction in neurotransmitter release occurs upon repeated stimulation with subsequent fade phenomenon. It should be noted, however, block of the prejunctional AChRs alone is not necessary and sufficient to induce fade; concomitant reduction in the safety of neurotransmission prejunctionally or postjunctionally must be present for it to be noticeable.[65] Although all clinically used nondepolarizing neuromuscular blocking drugs inhibit this prejunctional nicotinic AChR, as well as several other neuronal nicotinic AChRs, in the clinically relevant concentration range, succinylcholine neither activates nor inhibits the presynaptic α3β2 autoreceptor at clinically relevant concentrations.[53,85] However, the existence of the α3β2 autoreceptor at the prejunctional area has never been demonstrated by western blot or mRNA techniques. Thus, this prejunctional receptor has not been completely characterized.

This observation may be the reason for the typical lack of fade during succinylcholine-induced neuromuscular block. Succinylcholine, however, does not interact with α3β4 AChR found in autonomic ganglia.[53] It has also been shown that NDMRs reduce the hypoxic ventilatory response in partially paralyzed humans,[86] and the mechanism behind the depression might be related to inhibition of nicotine receptors on the carotid body.[11] Nicotinic α3, 7, and β2 AChRs have recently been documented in the human carotid body.[87] Whether the inhibition of these receptors plays a role in attenuated response to hypoxia drive needs further investigation. The motor nerve terminal is also known to bear several other receptors, such as opioid, adrenergic, dopamine, purine, and adenosine receptors, as well as receptors for endogenous hormones, neuropeptides, and a variety of proteins.[88,89] The physiologic roles of these receptors and the effects of anesthetics on them are unknown.

Neuromuscular Junction at Extremes of Age

NEWBORN

Just before birth, the AChRs are all clustered around the nerve in the junctional area, and minimal extrajunctional AChRs are present. The newborn postsynaptic membrane, itself, is not specialized, having almost no synaptic folds, a widened synaptic space, and a reduced number of AChRs.[14,19] The early postnatal AChR cluster appears as an oval plaque (Fig. 12.10). Within a few days, simplified folds appear. With continued maturation, the plaque is transformed to a multiperforated pretzel-like structure. The polyinnervated end plate is converted to a singly innervated junction because of a retraction of all but one terminal. In the adult, the terminals perfectly align with the AChR clusters. Morphologically, the postsynaptic membrane of the newborn and that from the patient with myasthenia gravis is not too different; the AChR number is decreased, and the postsynaptic folds are decreased. It is not surprising therefore that neurotransmission is not as efficient in the newborn and in patients with myasthenia gravis. For this reason, neonates and infants behave similar to patients with myasthenia gravis when NDMRs are administered to them.[90] In humans, maturation of the neuromuscular junction probably occurs at approximately 2 years of age.[90]

OLD AGE

With increasing life expectancy, typical changes associated with aging is a gradual loss of lean body mass and strength referred to as sarcopenia (Greek: sarco-flesh, penia- poverty), which has received increased attention recently.[91] These sarcopenic changes occur in association with denervation-like changes at the synapse and altered anabolic or growth factor signaling changes within muscle.[91-93] Old age-associated functional denervation, muscle wasting, and weakness is now well established.[91,92] Age-related morphologic changes include increase in length and area of the post-synaptic AChR, degenerating synaptic folds, and more invasion of synaptic folds by Schwann cells. The nerve terminals are thinned out and show terminal swelling with less apposition of the nerve to the synapse (see Fig. 12.10). Coupled with the morphologic changes in the neuromuscular junction that occur with aging, the functional changes that occur with it can include increased quantal content of neurotransmitter release and more rapid rundown of end-plate potential during stimulation of the preterminal neuron.[91-93] Regardless of these enumerated structured and functioned changes with aging, it appears that because of the superb margin of safety of neurotransmission, disability is not easily demonstrable by simple methods such as grip strength in most instances.[93] Despite the structural and functional changes associated with aging, the overall margin of safety is better in the older individual than in the neonate.[94] Even with these denervation-like changes in the elderly, there is no evidence that these patients are more prone to succinylcholine-induced hyperkalemia. There are also no studies confirming increased or decreased sensitivity to nondepolarizing blockers due to the neuromuscular junction changes. Some nondepolarizing neuromuscular blockers have prolonged effect in old age (e.g., vecuronium) due to pharmacokinetic causes.

Respiratory Physiology and Pathophysiology

BRIAN P. KAVANAGH† and GÖRAN HEDENSTIERNA

KEY POINTS

- Removal of carbon dioxide (CO_2) is determined by alveolar ventilation, not by total (minute) ventilation.
- Dead space ventilation can be dramatically increased in patients with chronic obstructive pulmonary disease and pulmonary embolism to more than 80% of minute ventilation.
- Breathing at small lung volumes increases airway resistance and promotes closure of airways.
- Hypoxemia can be caused by alveolar hypoventilation, diffusion impairment, ventilation-perfusion mismatch, and right-to-left shunt.
- Almost all anesthetics reduce skeletal muscle tone, which decreases functional residual capacity (FRC) to levels close to the awake residual volume.
- Atelectasis during anesthesia is caused by decreased FRC and the use of high inspired oxygen concentrations (FiO_2), including breathing oxygen before induction of anesthesia.
- General anesthesia causes ventilation-perfusion mismatch (airway closure) and shunts (atelectasis).
- Venous admixture is due to $\dot{V}_A/\dot{Q}$ mismatch (response to increased FiO_2) and shunts (unresponsive to increased FiO_2).
- Hypoxic pulmonary vasoconstriction is blunted by most anesthetics, and this results in increased ventilation-perfusion mismatching.
- Respiratory work is increased during anesthesia as a consequence of reduced respiratory compliance and increased airway resistance.

Respiratory Physiology Is Central to the Practice of Anesthesia

Respiratory function is inextricably linked to the practice of anesthesia. Adverse respiratory effects can occur during anesthesia,[1] and the most serious cases involve hypoxemia. These events range from intractable hypoxemia caused by loss of airway patency to postoperative respiratory depression from opioids or regional anesthesia.[2,3] In the absence of adverse outcomes, general anesthesia still has significant effects on respiratory function and lung physiology, documented by observations made in the operating and recovery rooms. Improved appreciation of anesthesia-induced physiologic alterations (e.g., mechanisms of bronchospasm,[4] impact of mechanical ventilation),[5] as well as pioneering developments in monitoring (e.g., pulse oximetry and capnography),[6] together are associated with the specialty of anesthesiology's emergence as a leader in patient safety.[7] Finally, integrative measures of respiratory function, ranging from exercise capacity,[8] spirometry to tissue oxygenation,[9] to global O_2 consumption,[8] may help predict outcomes following anesthesia and surgery.

Pulmonary Physiology in Health

The mechanisms by which anesthesia-associated respiratory dysfunction is caused can be determined with an examination of normal functions and mechanisms of respiration in health. We briefly review cellular respiration, whereby O_2 is consumed and CO_2 is produced, the transport of O_2 and CO_2 in the blood, and the principles by which the lung oxygenates blood and eliminates CO_2.

RESPIRATION IN THE CELL

The partial pressure of oxygen (PaO_2) in normal arterial blood is approximately 100 mm Hg, and decreases to 4 to 22 mm Hg in the mitochondrion, where it is consumed. Glucose ($C_6H_{12}O_6$) is converted into pyruvate (CH_3COCOO^-) and H^+ by glycolysis in the cytoplasm, and the pyruvate diffuses into the mitochondria and forms the initial substrate for Krebs cycle, which in turn produces nicotinamide adenine dinucleotide (NADH), as well as adenosine triphosphate (ATP), CO_2, and H_2O. The NADH is a key electron (and H^+) donor in the process of oxidative phosphorylation, wherein O_2 and adenosine diphosphate are consumed and ATP and H_2O are produced. Thus the net effect is oxidation of glucose to produce energy (ultimately as ATP), H_2O, and CO_2.[10]

TRANSPORT OF O_2 IN THE BLOOD

O_2 reaches the cells following transport by arterial blood, and the overall delivery of O_2 ($\dot{D}O_2$) is the product of the arterial blood O_2 content (CaO_2) and blood flow (cardiac output, $\dot{Q}$) as

---

†Deceased.

$$\dot{D}O_2 = CaO_2 \times \dot{Q}$$

Oxygen is carried in the blood in two forms: O_2 bound to hemoglobin (the vast bulk), and O_2 dissolved in the plasma, and the content is expressed as the sum of these components:

$$CaO_2 = \begin{bmatrix} (SaO_2 \times Hb \times O_2 \ \ combining \ \ capacity \ \ of \ \ Hb) \\ + (O_2 \ \ solubility \times PaO_2) \end{bmatrix}$$

where CaO_2 (O_2 content) is the milliliters of O_2 per 100 mL of blood, SaO_2 is the fraction of hemoglobin (Hb) that is saturated with O_2, O_2-combining capacity of Hb is 1.34 mL of O_2 per gram of Hb, *Hb* is grams of Hb per 100 mL of blood, Pao_2 is the O_2 tension (i.e., dissolved O_2), and solubility of O_2 in plasma is 0.003 mL of O_2 per 100 mL plasma for each mm Hg Pao_2

The binding of O_2 to hemoglobin is a complex, allosteric mechanism. Important insights can be gained by understanding how characteristic abnormalities of blood O_2 carriage (e.g., carbon monoxide [CO] poisoning, methemoglobinemia) affect O_2 tension, content, and delivery.

Methemoglobin (MetHb), formed by the oxidation to Fe^{3+} (ferric) instead of the usual Fe^{2+} (ferrous) iron, is less able to bind O_2, resulting in diminished O_2 content and less O_2 delivery. Here, the Pao_2 (in the absence of lung disease) will be normal: if the O_2 content is calculated from the Pao_2, it will appear normal, but if directly measured, it will be low. In contrast, MetHb level will be elevated. In severe cases, lactic acidosis develops because of impaired O_2 delivery. In addition, because MetHb has a blue-brown color, the patient will appear blue, even if the fraction of MetHb is modest; specialized oximetry can separately measure MetHb levels.[11,12] The apparent cyanosis is not responsive to supplemental O_2, and therapy involves converting (i.e., reducing) the MetHb to Hb (e.g., by using methylene blue). Important medical causes of MetHb include benzocaine, dapsone, or in susceptible patients, inhaled nitric oxide (NO).

In CO poisoning, the CO binds to Hb, with far greater (over 200-fold) avidity than molecular O_2, tightly forming CO-Hb and resulting in two main effects.[13] First, formation of CO-Hb results in fewer sites available for O_2 binding, and this reduces the blood O_2 content. Second, the formation of CO-Hb causes conformational changes in the Hb molecule such that the tendency to release bound O_2 is reduced. This effect corresponds to a leftward shift of the Hb-O_2 dissociation curve, and although this aspect of CO binding does not reduce the O_2 content or "global" delivery of O_2, it does reduce the release of O_2 and its local delivery to the cells. Because the color of CO-Hb closely resembles that of O_2-Hb, the color of the blood (and the patient) is bright red; however, as with MetHb, the PaO_2 will be normal (assuming no pulmonary disease) as will be the calculated CaO_2; however, the measured CaO_2 will be low and if severe, a lactic acidosis will be present. Modern pulse oximeters can distinguish between Hb-O_2 and CO-Hb.[13]

Finally, the *Bohr effect* refers to a shift of the Hb-O_2 dissociation curve caused by changes in CO_2 or pH.[14] In the systemic capillaries, the Pco_2 is higher than in the arterial blood (and the pH correspondingly lower) because of local CO_2 production. These circumstances shift the Hb-O_2 dissociation curve to the right, which increases the offloading of O_2 to the tissues. The opposite occurs in the pulmonary capillaries; here, the Pco_2 is lower (and the pH correspondingly higher) because of CO_2 elimination, and the dissociation curve is shifted to the left to facilitate O_2 binding to Hb.

TRANSPORT OF CO_2 IN THE BLOOD

CO_2 is produced by metabolism in the mitochondria, where the CO_2 levels are highest. The transport path (involving progressively decreasing pressure gradients) is from mitochondria through cytoplasm, into venules, and finally, in mixed venous blood from where it is eliminated through the alveoli. In the blood, CO_2 is transported in three main forms: dissolved (reflected as $Paco_2$, partial pressure; accounts for approximately 5% of transported CO_2), bicarbonate ion (HCO_3–; almost 90%), and carbamino CO_2 (CO_2 bound to terminal amino groups in Hb molecules; approximately 5%).[10] The usual quantities of CO_2 in the arterial and (mixed) venous blood are approximately 21.5 and 23.3 mmol of CO_2 per liter of blood, respectively.

Breathing O_2 can sometimes induce hypercapnia, as occurs in patients with severe chronic lung disease who are breathing supplemental O_2. Although traditionally thought to occur because increased Pao_2 reduces ventilatory drive, this is now thought not to be the case,[15] resulting instead from the Haldane effect, as well as from impairment of hypoxic pulmonary vasoconstriction (HPV). The Haldane effect[16] is the difference in the amount of CO_2 carried in oxygenated versus deoxygenated blood, and two mechanisms explain this. First, increased Pao_2 decreases the ability to form carbamino compounds—reducing the amount of CO_2 bound to Hb—thereby raising the amount of dissolved CO_2 (i.e., elevated Pco_2). Second, the amino acid histidine, which has an imidazole group that is an effective H^+ buffer at physiologic pH, is an important linking molecule between heme groups and the Hb chains. Increasing the partial pressure of oxygen (PO_2) increases the amount of O_2 bound to Hb; this changes the conformation of the Hb molecule, which in turn alters the heme-linked histidine and reduces its H^+ buffering capacity. Therefore, more H^+ is free (not buffered) and binds to HCO_3–, releasing stored CO_2. Impairment of HPV by elevated O_2 allows increased perfusion to poorly ventilated regions; this has the effect of decreasing perfusion (and delivery of CO_2) to better ventilated regions, diminishing the efficiency of CO_2 exhalation. Patients with impaired ability to increase alveolar ventilation ($\dot{V}_A$) cannot compensate for the increased CO_2 availability, and therefore, in these patients, adding supplemental O_2 can result in elevated $Paco_2$.

OXYGENATION IN THE PULMONARY ARTERY

Systemic venous blood (central venous blood) enters the right ventricle via the right atrium. The O_2 saturation (SO_2) differs among the major veins: higher venous SO_2 reflects greater blood flow, less tissue oxygen uptake, or both.[17] SO_2 is usually higher in the inferior vena cava (IVC) than in the superior vena cava (SVC), possibly because of the high renal and hepatic flow relative to O_2 consumption. In the right ventricle, the central venous blood ($S_{cv}O_2$) from the SVC and IVC is joined by additional venous blood from the coronary circulation (via the coronary sinuses). In the right ventricle, an additional small amount of venous drainage from the myocardium enters through the thebesian veins, and as all this

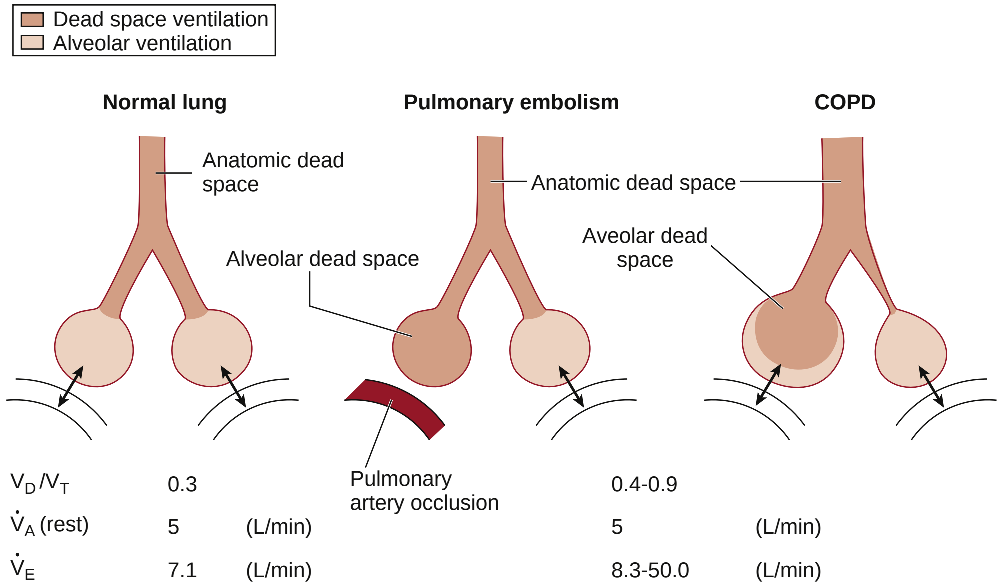

Fig. 13.1 Dead space and alveolar ventilation in normal and diseased lungs. Either cessation of blood flow or excessive alveolar ventilation relative to perfusion will cause an increase in dead space (V_D). If V_D is increased, a large compensatory increase in minute ventilation is required to preserve $\dot{V}_A$. V_D/V_T, dead space to tidal volume ratio; $\dot{V}_A$, alveolar ventilation; $\dot{V}_E$, minute ventilation. $\dot{V}_E = \dot{V}_A + f \times V_D$. *Double arrows* indicate normal CO_2 exchange. *COPD*, Chronic obstructive pulmonary disease. (From Hedenstierna G. *Respiratory measurement*. London: BMJ Books; 1998:184; see also book review of *Respiratory Measurement in Thorax* 1998;53:1096.)

venous blood enters the pulmonary artery, it is well mixed and is termed *mixed-venous blood* (S_vO_2); thus $S_vO_2 < S_{cv}O_2$, although the trends of each usually run in parallel.[18]

Ventilation

Ventilation refers to the movement of inspired gas into and exhaled gas out of the lungs.

ALVEOLAR VENTILATION

Fresh gas enters the lung by cyclic breathing at a rate and depth (tidal volume, V_T) determined by metabolic demand, usually 7 to 8 L/min.[19] While most inspired gas reaches the alveoli, some (100-150 mL) of each V_T remains in the airways and cannot participate in gas exchange. Such dead space (V_D) constitutes approximately one third of each V_T.[20] Anatomic V_D is the fraction of the V_T that remains in the "conducting" airways, and physiologic V_D is any part of a V_T that does not participate in gas exchange (Fig. 13.1).

For a single tidal volume (V_T, mL), the following is true:

$$V_T = V_A + V_D$$

The product of V_T (mL) times the respiratory rate (per minute) is the minute ventilation ($\dot{V}_E$). Aggregated over time, minute ventilation ($\dot{V}_E$, mL/min) is:

$$\dot{V}_E = \dot{V}_A + f \times V_D$$

The portion of the $\dot{V}_E$ that reaches the alveoli and respiratory bronchioles each minute and participates in gas exchange is called the *alveolar ventilation* ($\dot{V}_A$), and it is approximately 5 L/min. Because this is similar to the blood flow through the lungs (i.e., the cardiac output, also 5 L/min), the overall alveolar ventilation-perfusion ratio is approximately 1.

DEAD SPACE VENTILATION

Maintenance of $Pa{CO_2}$ is a balance between CO_2 production ($\dot{V}CO_2$, reflecting metabolic activity) and alveolar ventilation ($\dot{V}_A$). If $\dot{V}_E$ is constant but V_D is increased, $\dot{V}_A$ will naturally be reduced, and the $Pa{CO_2}$ will therefore rise. Therefore, if V_D is increased, $\dot{V}_E$ must also increase to prevent a rise in $Pa{CO_2}$. Such elevations in V_D occur when a mouthpiece or facemask is used, and in such cases, the additional V_D is termed "apparatus deadspace" (which can be up to 300 mL; anatomic V_D of the airways is 100-150 mL).[21]

Increases in the volume of the conducting airways (e.g., bronchiectasis) increase the overall V_D only slightly. Far more significant increases in V_D occur when perfusion to a large number of ventilated alveoli is interrupted, as occurs in a pulmonary embolus (see Fig. 13.1). Indeed, with multiple pulmonary emboli, V_D/V_T can exceed 0.8 (2.7-fold normal). In such a case, to maintain a normal $\dot{V}_A$ (5 L/min), the $\dot{V}_E$ would have to increase (also 2.7-fold) to almost 20 L/min. This effort would cause considerable dyspnea, in addition to the dyspnea induced by the lowered PaO_2.

Obstructive lung disease can result in diversion of inspired air into (nonobstructed) ventilated, but poorly perfused, regions of the lung. This results in local excesses of ventilation versus perfusion (high $\dot{V}_A/\dot{Q}$ ratio) in such regions,[22] which is equivalent to an increase in V_D/V_T (see Fig. 13.1). Patients with severe chronic obstructive pulmonary disease (COPD) may have a V_D/V_T ratio of up to 0.9, and would have to hyperventilate massively (30-50 L/min) to maintain normal $Pa{CO_2}$, which is not possible where ventilator reserve is diminished. Such patients demonstrate reduced $\dot{V}_A$ but often have an elevated $\dot{V}_E$. An important compensatory mechanism is that a lower level of $\dot{V}_A$ will maintain stable CO_2 excretion where the $Pa{CO_2}$ is increased (Box 13.1).

BOX 13.1 Alveolar Gas Equations

Alveolar Oxygen Tension (P_{AO_2})

$$P_{AO_2} = PIO_2 - \frac{P_{ACO_2}}{R} + \left[P_{ACO_2} \times FiO_2 \times \frac{1-R}{R}\right]$$

where PIO_2 is inspired oxygen tension, $PACO_2$ is alveolar CO_2 tension (assumed to equal arterial PCO_2), R is the respiratory exchange ratio (normally in the range of 0.8-1.0), and FiO_2 is the inspired oxygen fraction. The term within brackets compensates for the larger O_2 uptake than CO_2 elimination over the alveolar capillary membranes.

A simplified equation can be written without the compensation term:

$$P_{AO_2} = PIO_2 - \frac{P_{ACO_2}}{R}$$

Alveolar Ventilation

Alveolar ventilation ($\dot{V}_A$) can be expressed as

$$\dot{V}_A = f \times (V_T - V_{DS})$$

where *f* is breaths/min, V_T is tidal volume, and V_{DS} is physiologic dead space.

Alveolar ventilation can also be derived from:

$$\dot{V}_{CO_2} = c \times \dot{V}_A \times F_{ACO_2}$$

where $\dot{V}_{CO_2}$ is CO_2 elimination, *c* is a conversion constant, and $FACO_2$ is the alveolar CO_2 concentration.

If $\dot{V}_A$ is expressed in L/min, $\dot{V}_{CO_2}$ in mL/min, and $FACO_2$ is replaced by $PACO_2$ in mm Hg, *c* = 0.863. By rearranging:

$$\dot{V}_A = \frac{\dot{V}_{CO_2} \times 0.863}{P_{ACO_2}}$$

Static Lung Volumes—Functional Residual Capacity

The amount of air in the lungs after an ordinary expiration is called *functional residual capacity* (FRC; Fig. 13.2); it is usually 3 to 4 L and occurs because of the balance of inward (lung) forces and outward (chest wall) forces. The inward force is the "elastic recoil" of the lung and emanates from the elastic lung tissue fibers, contractile airway smooth muscle, and alveolar surface tension. The outward force is developed by passive recoil from the ribs, joints, and muscles of the chest wall. FRC is greater with increased height and age (loss of elastic lung tissue), and smaller in women and in obesity.[19,23]

There are two reasons why maintenance of gas in the lung at end-expiration (i.e., FRC) is important. First, inflating an already opened (inflated) lung is easier than when the lung is deflated. This is because complete collapse results in liquid-only surfaces interfacing in alveoli (high surface tension), whereas alveoli in partially inflated lung have air-liquid interfaces (lower surface tension). Second, although perfusion in the lung is phasic, the frequency is rapid and the oscillations in flow are low, resulting in nearly continuous flow. Ventilation is different: the frequency is far slower and the size of the oscillations far larger. If the lung (or large parts of it) completely deflate between breaths, the blood flowing from closed alveoli (that contain zero O_2) would have very low SO_2 (the same as mixed venous blood); this would mix into the overall blood flow from the lungs and cause a major O_2 desaturation after every exhalation.

Respiratory Mechanics

The study of respiratory mechanics tells us how inspired air is distributed within the lung and permits quantitation of the severity of lung disease. The components of overall impedance to breathing results from elastance (the reciprocal of compliance), resistance, and inertia.

COMPLIANCE OF THE RESPIRATORY SYSTEM

The lung is like a rubber balloon that can be distended by positive pressure (inside) or negative pressure (outside). Under normal circumstances, inflation of the lung is maintained because although the pressure inside (alveolar pressure) is zero, the outside pressure (i.e., the pleural pressure) is sufficiently negative. The net distending pressure, which is the difference of the (positive) airway pressure (P_{AW}) and the (negative) pleural pressure (P_{PL}) is termed the *transpulmonary pressure* (P_{TP}). Thus:

$$P_{TP} = P_{AW} - P_{PL}$$

Clearly, increasing the P_{AW} increases the P_{TP}. In addition, lowering the P_{PL} (which is usually negative and making it more negative) also increases the P_{TP}.

Compliance—the reciprocal of elastance—is the term that expresses how much distention (volume in liters) occurs for a given level of P_{TP} (pressure, cm H_2O); it is usually 0.2 to 0.3 L/cm H_2O.[24] However, although higher values of P_{TP} maintain greater levels of lung opening, the relationship—as with most elastic structures—between applied pressure and resultant volume is curvilinear (Fig. 13.3).[24] Lung compliance depends on the lung volume; it is lowest at an extremely low or high FRC (see Fig. 13.3). In lung diseases characterized by reduced compliance (e.g., ARDS, pulmonary fibrosis, or edema), the pressure-volume (PV) curve is flatter and shifted to the right (Fig. 13.4).[24] In contrast, although emphysema involves the loss of elastic tissue, the overall loss of lung tissue (as seen on computed tomography [CT] scanning)[25] means that the compliance is increased; the PV curve is therefore shifted to the left and is steeper (see Fig. 13.4).[24]

Chest wall impedance is not noticed during spontaneous breathing because the respiratory "pump" includes the chest wall. Chest wall mechanics can be measured only if complete relaxation of the respiratory muscles can be achieved[26]; however, during mechanical ventilation, the respiratory muscles can be completely relaxed. As the lung is inflated by P_{AW}, the properties of the chest wall will determine the resulting change in P_{PL}. Under these circumstances, the increase in lung volume per unit increase in P_{PL} is the chest wall compliance. Values of chest wall compliance are about the same as that of the lung and are reduced with obesity, chest wall edema, pleural effusions, and diseases of the costovertebral joints.[26]

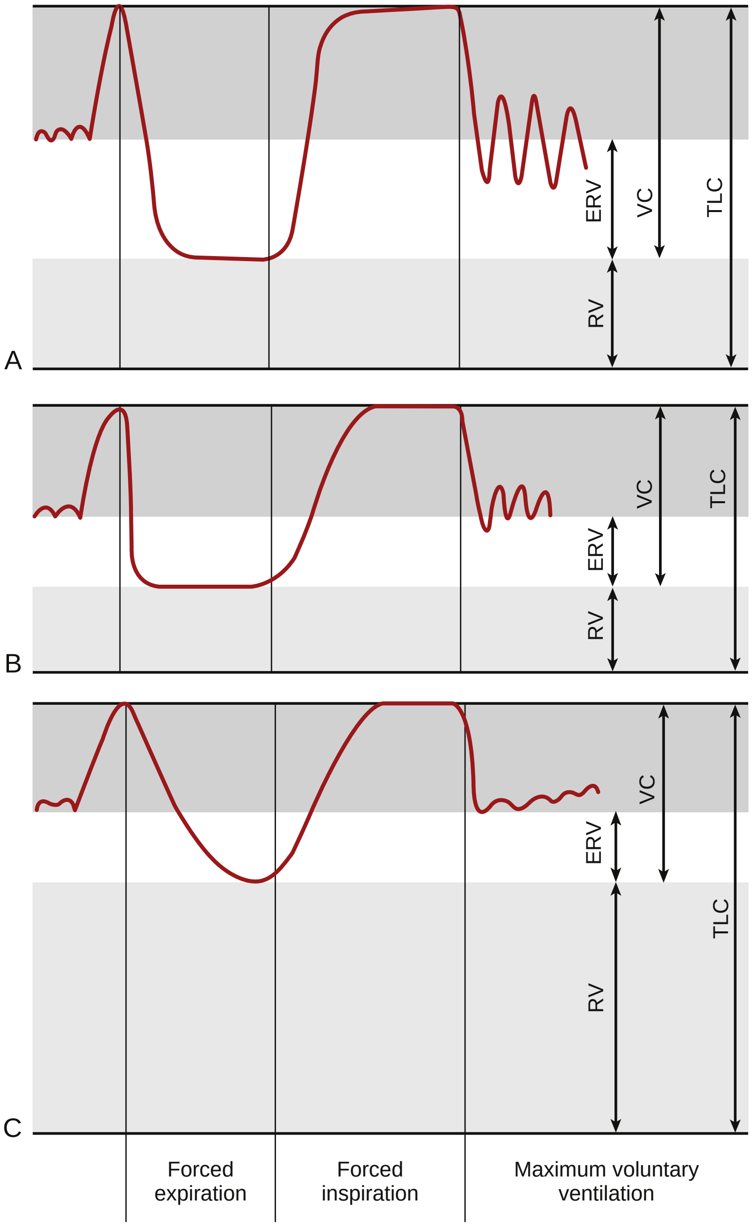

Fig. 13.2 (A) Ventilation and lung volumes in a healthy subject with normal lungs. (B) A patient with restrictive lung disease. (C) A patient with chronic obstructive pulmonary disease (COPD). In restrictive disease, the vital capacity *(VC)* is decreased and expiratory flow rate is increased (i.e., steeper than the normal slope of the forced expiratory curve). In COPD, the residual volume *(RV)* is increased, the VC is reduced, and forced expiration is slowed. *ERV,* Expiratory reserve volume; *TLC,* total lung capacity. (From Hedenstierna G. *Respiratory measurement*. London: BMJ Books; 1998:184; see also book review of *Respiratory Measurement in Thorax* 1998;53:1096.)

RESISTANCE OF THE RESPIRATORY SYSTEM

Airways

Resistance impedes airflow into (and out of) the lung. The major component of resistance is the resistance exerted by the airways (large and small), and a minor component is the sliding of lung and the chest wall tissue elements during inspiration (and expiration).[27] Resistance is overcome by (driving) pressure. In spontaneous breathing, driving pressure will be the P_{PL}; in positive pressure ventilation, the driving pressure will be the difference between the pressures applied to the endotracheal tube (P_{AW}; "source") and the alveolus (P_{ALV}; "destination"). Resistance (R) is calculated as driving pressure (ΔP) divided by the resultant gas flow (F):

$$R = \frac{\Delta P}{F}$$

The value of airway resistance is approximately 1 cm H_2O/L/sec, and is higher in obstructive lung disease (e.g., COPD, asthma); in severe asthma, it is elevated approximately tenfold.[28] The presence of an endotracheal tube adds a resistance of 5 (or 8) cm H_2O/L/min for a tube with internal diameter of size 8 (or 7) cm.[29] For any tube for which the airflow is laminar (smooth, streamlined), the resistance increases in direct proportion to the tube length and increases dramatically (to the fourth power) as the diameter of the tube is reduced.

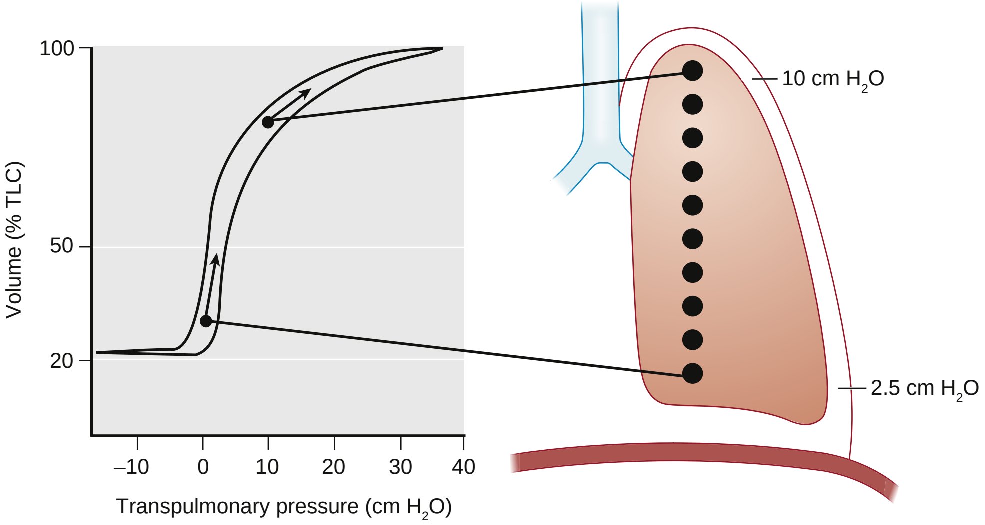

Fig. 13.3 The pressure-volume relationships of the lung. The relationship is curvilinear (typical for an elastic structure). The pleural pressure is lower (more subatmospheric) in the upper regions. In the upright subject, the transpulmonary pressure ($P_{TP} = P_{AW}–P_{PL}$) is higher in apical than in basal regions. This results in different positions on the pressure volume curve of the upper (flatter, less compliant) versus lower (steeper, more compliant) lung regions. Thus lower lung regions expand more (i.e., receive more ventilation) for a given increase in transpulmonary pressure than upper units. *TLC,* Total lung capacity.

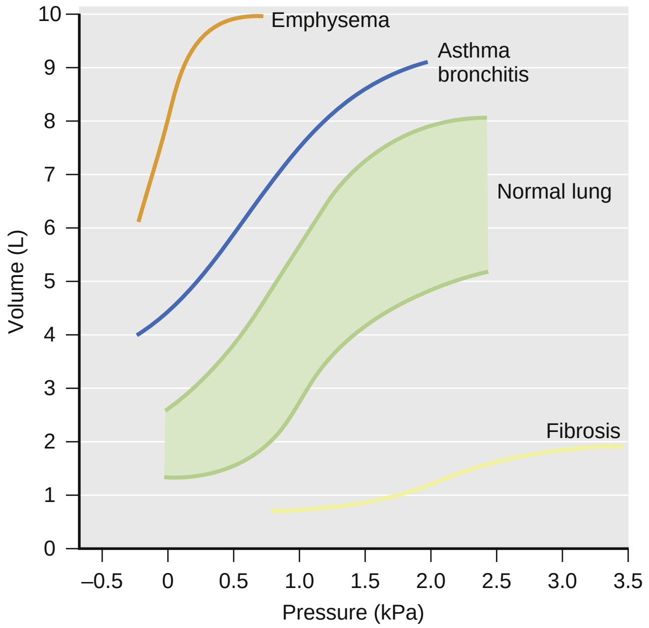

Fig. 13.4 Pressure-volume curves of the lung in healthy and lung-diseased patients. In fibrosis, the slope of the curve is flatter, reflecting considerable increases in pressure variation and in respiratory work. In asthma or bronchitis, there is a parallel *(upward)* shift of the pressure-volume curve, indicating an increase in lung volume but no change in compliance. In emphysema, the slope of the curve is steeper, reflecting tissue loss and possible increased compliance. However, in emphysema, asthma, or bronchitis, the airway resistance is increased; this increases work of breathing and overrides any benefit from increased compliance. (From Hedenstierna G. *Respiratory measurement.* London: BMJ Books; 1998:184; see also book review of *Respiratory Measurement in Thorax* 1998;53:1096.)

Two factors explain why most (approximately 80%) of the impedance to gas flow occurs in the large airways.[27] First, as bronchi progressively branch, the resistances are arranged in parallel and the total cross-sectional area at the level of the terminal bronchioles adds up to almost tenfold that at the trachea. Second, in tubes that are large, irregular or branched, the flow is often turbulent, not laminar. When flow is laminar:

$$F_{(lam)} = \frac{\Delta P}{R}$$

In contrast, when flow is turbulent:

$$F_{(turb)} = \frac{\Delta P}{R^2}$$

Therefore, for a given radius, far more pressure is required to achieve comparable flow where flow is turbulent; thus the effort required is greater and if prolonged or severe, respiratory failure is more likely.

Several factors can alter airflow resistance. First, resistance lessens as lung volume increases; this is intuitive, as increasing volume (positive pressure or spontaneous breathing) stretches the diameter of the airways. Because this is the key determinant of resistance, the resistance falls to a small extent. The opposite occurs with exhalation (Fig. 13.5). However, as lung volume approaches residual volume (RV)—as can happen during anesthesia—the airways are narrowed in parallel with the compressing lung tissue and the resistance rises exponentially. These effects are apparent with active or passive ventilation. Second, active ventilation has additional effects. Forced expiration can compress small airways (i.e., that do not contain cartilage).[27] In addition, forced expiration can cause turbulent flow in small airways in patients with COPD, precipitously dropping pressure in the lumen and thereby narrowing the bronchioles[30] and resulting in expiratory flow limitation and, after multiple breaths, eventual "dynamic hyperinflation."[31] Expiring against resistance (or pursed-lips breathing) is sometimes used by those with COPD to make breathing easier. This works by increasing expiratory resistance and slowing expiration. The slowed expiration reduces the pressure gradient driving expiration (i.e., pressure highest in the alveolus, lower toward the mouth). Therefore, the point along the airway tree at which pressure inside the airway has decreased to less than that outside the

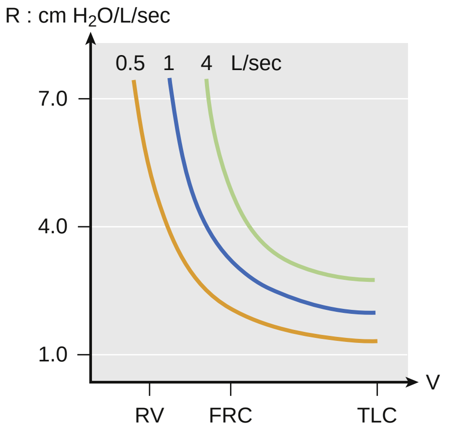

Fig. 13.5 Schematic drawing of airflow resistance against lung volume at different flow rates. As lung volume falls, the resistance to flow increases; the steepness of this increase is far greater at lung volumes below functional residual capacity *(FRC)*. In addition, higher airflow rates are associated with greater resistance. At extremely low lung volume, the resistance is comparable to values seen in moderate to severe asthma (6-8 cm $H_2O \times l^{-1} \times s$). *RV,* Residual volume; *TLC,* total lung capacity.

airway (equal to pleural pressure) is moved from smaller collapsible airways toward the mouth to noncollapsible, cartilaginous airways (Fig. 13.6); this prevents collapse of the smaller airways, which are vital for proper gas exchange.[32]

The large airways (i.e., pharynx, larynx, and trachea) are outside the chest wall. During inspiration, the intrathoracic airways are exposed to extraluminal pressure (i.e., P_{PL}) that is less than the lumen pressure; in contrast, the extrathoracic airways are exposed to lumen pressure that is less than the extraluminal (i.e., atmospheric) pressure.[27] This feature, coupled with downward stretch induced by inspiration, narrows the large extrathoracic airways; in the presence of preexisting narrowing (e.g., thyroid enlargement or tumor, paralyzed vocal cord, epiglottitis), this can critically reduce the cross-sectional area.

Tissue

Although not intuitively obvious, resistance of the lung tissue is the applied pressure on tissue divided by the resulting velocity of tissue movement. There are various approaches to determining this in humans, including separately

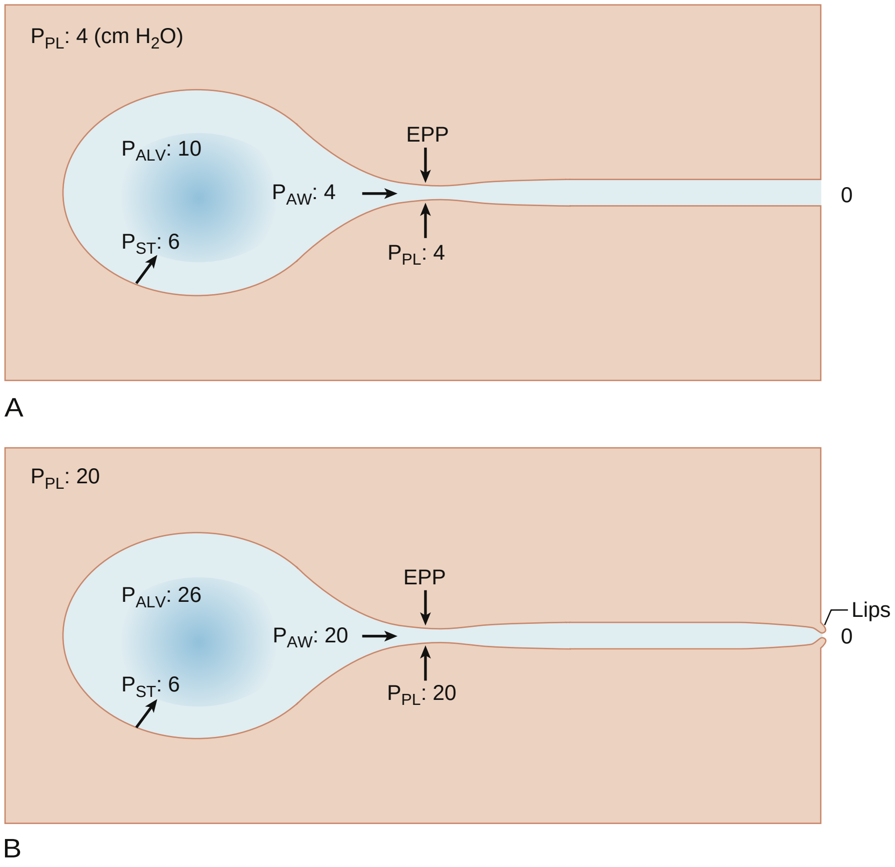

Fig. 13.6 Schematic drawings of the equal pressure point *(EPP)* concept and dynamic compression of airways. (A) Slightly forced expiration during otherwise normal conditions. With the application of some expiratory muscle effort, pleural pressure *(P_{PL})* is positive, 4 cm H_2O (0.4 kPa). The elastic recoil pressure *(P_{ST})* of the alveoli (6 cm H_2O) and the pleural pressure add together to yield intraalveolar pressure *(P_{ALV})* (10 cm H_2O). This causes expiratory flow. At some point downstream toward the airway opening, airway pressure *(P_{AW})* has dropped by 6 cm H_2O, so intraluminal pressure and pleural, extraluminal pressure are the same. This is the EPP. From this point to the mouth, intraluminal airway pressure is lower than the surrounding, extraluminal pressure and the airway may be compressed. (B) An attempt to stabilize the airway by so-called “pursed-lip” breathing. The increased resistance to expiratory flow requires increased expiratory effort to maintain gas flow. Thus pleural pressure is increased in comparison to the normal conditions (P_{PL} = 20 cm H_2O). Alveolar elastic recoil pressure (P_{ST}) is the same as in the earlier condition, provided that lung volume is the same. If expiratory flow is of the same magnitude as during normal breathing, pressure along the airway falls to the same extent as during normal breathing. Thus the EPP will have the same location as during normal breathing, and no stabilization of the airway has been achieved. The two ways of moving the EPP toward the mouth and to less collapsible airways is by raising alveolar recoil pressure (P_{ST}) by an increase in lung volume or by lowering the expiratory flow rate so that the pressure drop along the airway tree is slowed down.

considering the PV characteristics using plethysmography (where the area of the PV curve corresponds to work against total pulmonary resistance) and esophageal pressure (where the area of the PV curve corresponds to work against "tissue" resistance).[33] Alternative approaches mathematically model the lung responses to varying respiratory frequencies.[34] Lung tissue resistance amounts to 20% of the total resistance to breathing; it can be increased threefold or fourfold in chronic lung disease[35] and is reduced by panting respirations.[36] Finally, in adult respiratory distress syndrome (ARDS) the chest wall resistance is increased.[37]

INERTIA OR ACCELERATION OF GAS AND TISSUE

A final component of the total impedance to breathing is inertance, or the pressure required to accelerate air and tissue during inspiration and expiration. This component is minor, however, and can hardly be measured under normal breathing, regardless of whether the lungs are healthy. Nonetheless, tissue inertia is large during rapid ventilation,[38] and it could be important during the rapid, shallow breathing characteristic of weaning failure or during high-frequency oscillation.

Distribution of Inspired Gas

Inspired gas is not evenly distributed throughout the lung; naturally, more gas enters those lung units that expand most during inspiration. In the resting lung, the basal (dependent) regions are less aerated than the apical (nondependent) regions; therefore, they have the capacity to undergo greater expansion. During inspiration, most gas goes to the basal units (dorsal, when supine; lower right lung when in the right lateral position).[39] This distribution is because of the compliance properties of the lung and the effects of position on the distribution of the distending pleural pressure (i.e., the P_{PL} gradient). These changes are not related to the properties of the inspired gas.

In the upright position, the P_{PL} is less negative at the base of the lung than at the apex. Because the alveolus pressure (P_A) is uniform throughout the lung, the distending P_{TP} is greater at the apex; therefore, before inspiration commences, the apical lung is more open (and is less compliant) than the basal lung (Figs. 13.3 and 13.7). With inspiration, the contracting diaphragm lowers the P_{PL} by a comparable amount in all areas of the pleural surface (because of the fluid-like behavior of normal lung[39]) and distends the basal more than the apical regions (see Figs. 13.3 and 13.7). Because the pleural pressure gradient is oriented according to gravity, the distribution of ventilation changes with body position.

The P_{PL} gradient exists because lung density, gravity, and conformation of the lung to the shape of the thorax[40] result in crowding of the basal lung tissue, making the local P_{PL} less negative in the basal regions. Because the density of normal lung is approximately 0.3, P_{PL} will become more positive by 0.3 cm H_2O for each downward vertical

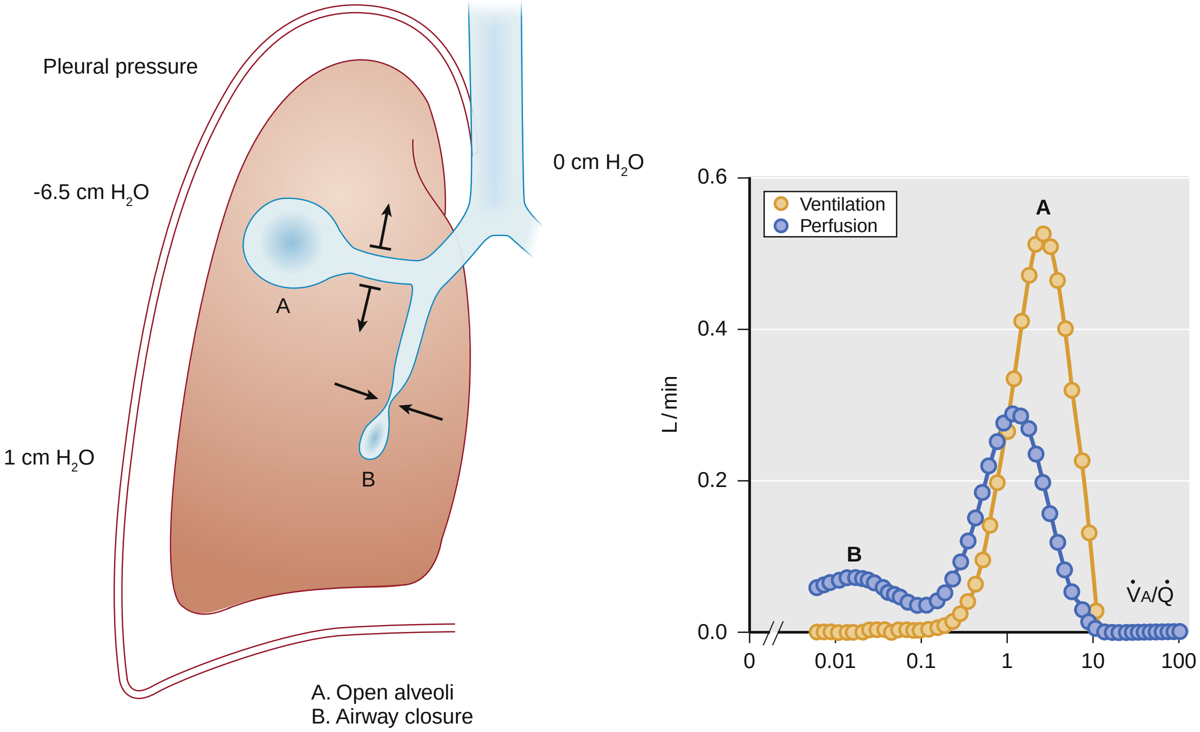

Fig. 13.7 Schematic of regional alveolar and airway volume at an upper *(A)* and a lower *(B)* lung level *(left panel)*. There is a vertical pleural pressure (P_{PL}) gradient between the uppermost and lowermost regions (–6.5 to 1 = –7.5 cm H_2O). Airway pressure (P_{AW}) is atmospheric, or 0 cm H_2O throughout; thus, in the upper regions, $P_{AW} > P_{PL}$ maintains airways open. In contrast, in the lower regions, $P_{PL} > P_{AW}$ causes airway closure—potentially exacerbated by subsequent alveolar gas absorption behind the occluded airway. The *right panel* shows the distribution of ventilation and perfusion ratios from the multiple inert gas elimination technique. A "normal" mode of ventilation and blood flow *(A)* can be seen corresponding to the open and ventilated alveoli in the upper parts of the lung. In addition, there is a range of low $\dot{V}_A/\dot{Q}$ ratios with more perfusion than ventilation *(B)*. This pattern is compatible with intermittent airway closure during breathing.

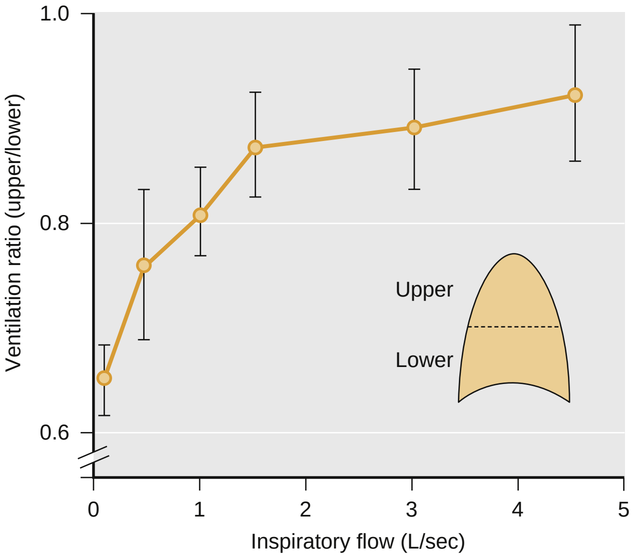

Fig. 13.8 Distribution of ventilation to upper versus lower lung regions as inspiratory flow is altered. At low flow, the bulk of the airflow goes to the lower regions. At higher flow rates (e.g., during exercise) the distribution is more even, ensuring more efficient use of all alveolar-capillary membranes for gas transfer (provided that pulmonary blood flow shows a similar distribution pattern).

centimeter, and more so with injured or edematous lungs. Indeed, experimentally induced weightlessness decreases inhomogeneity in the distribution of ventilation,[41] but does not eliminate it; therefore, nongravitational (e.g., tissue, airway) factors also play a role.[42]

Although the vertical height of the lung is the same in the prone and supine positions, the vertical gradient P_{PL} is less when prone,[43] perhaps because the mediastinum compresses the dependent lung when supine but rests on the sternum when prone.[44] A more even distribution of inspired gas—with improved oxygenation—in the prone position was predicted by Bryan in 1974[44]; this has been confirmed experimentally.[45,46]

During low-flow states (e.g., at rest), distribution is determined by differences in compliance and not by airway resistance. Because compliance at the start of inflation is less in the (already more aerated) apex, ventilation is preferentially directed to the base. In contrast, at high airflow, resistance (not compliance) is the key determinant of distribution; because the resistance is lower in upper, more expanded lung regions, increasing flow rate equalizes the distribution of ventilation, as shown by distribution of ^{133}Xe gas in humans (Fig. 13.8).[47,48] This is important during exercise or stress because greater amounts of the alveolar-capillary surface area will be used.

AIRWAY CLOSURE

Expiration causes the airways to narrow, and deep expiration can cause them to close. The volume remaining above RV where expiration below FRC closes some airways is termed *closing volume* (CV), and this volume added to the RV is termed the *closing capacity* (CC; i.e., the total capacity of the lung at which closing can occur).[49] Closure of airways during expiration is normal and is potentiated by increasing P_{PL}, especially with active expiration. When P_{PL} exceeds

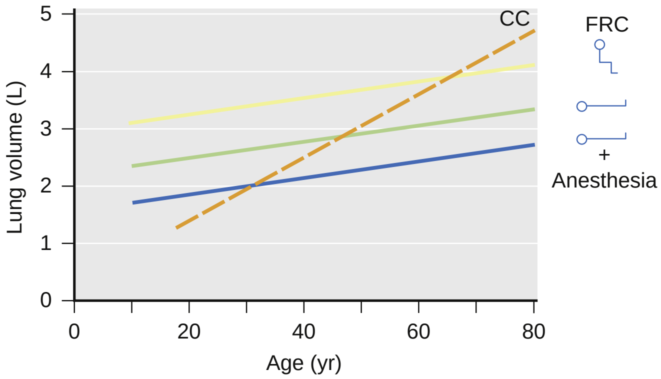

Fig. 13.9 Resting functional residual capacity *(FRC)* and closing capacity *(CC)*. FRC increases with age (because of loss of elastic tissue), and superimposed upon this is a step decrease in FRC with supine position (because of diaphragm elevation by abdominal contents), and a further decrease with anesthesia in the supine position. The CC is also increased with age, but far more steeply, causing airway closure above FRC in upright subjects (>65 yr) and in supine subjects (>45 yr). This relationship between CC and FRC explains decreasing oxygenation with age.

the P_{AW}, the airway—if collapsible—will tend to close, and this usually commences at the bases because the basal P_{PL} is greatest (see Fig. 13.7).

Three applications of this important principle are of key relevance to anesthesia. First, airway closure depends on age: in youth, the closure does not occur until expiration is at or near RV, whereas with older age, it occurs earlier in expiration (i.e., at higher lung volumes). This occurs because P_{PL} is on average more "positive" (i.e., atmospheric, equal to P_{AW}) as age increases. Closing can occur at or above FRC in individuals aged 65 to 70 years,[50] such that dependent regions will undergo closure during normal expiration. This may be the major reason why oxygenation decreases with age. Second, in the supine position, FRC is less than when upright, but CC is unchanged; therefore, exhalation of a usual V_T (from FRC) encroaches on CC in a supine 45-year-old, and closure may be continuous in a supine 70-year-old (Fig. 13.9). Finally, COPD increases the lung volume at which closure occurs, possibly exacerbated by airway edema and increased bronchial tone.[49]

DIFFUSION OF GAS

Gas moves in the large and medium-sized airways by bulk flow (i.e., convection), meaning that the gas molecules travel together at a given mean velocity according to a driving pressure gradient. Flow is through multiple generations of bronchi, and the net resistance falls with each division. After the 14th generation, airways merge with alveoli and participate in gas exchange (respiratory bronchioles). The cross-sectional area expands massively (trachea, 2.5 cm^2; 23rd generation bronchi, 0.8 m^2; alveolar surface, 140 m^2),[51] resulting in a sharp drop in overall resistance. Because the number of gas molecules is constant, the velocity falls rapidly, which by the time the gas enters the alveoli is miniscule (0.001 mm/s); it is zero when it reaches the alveolar membrane. The velocity of the gas entering the alveolus is slower than the diffusion rates of O_2 and CO_2; therefore, diffusion—not convection—is necessary for transport in the distal airways and alveoli. Indeed,

CO_2 is detectable at the mouth after just seconds of breath-holding, because of rapid diffusion and because of cardiac oscillations (i.e., mixing).

Gas mixing is complete in the alveoli of a normal lung during normal breathing. However, if the alveolus expands (e.g., emphysema), the diffusion distance may be too great to allow complete mixing, potentially leaving a layer of CO_2-rich gas lining the alveolar membrane and a core of O_2-rich gas in the alveolus. This represents a “micro” version of inhomogeneous distribution of ventilation.[52]

Perfusion

The pulmonary circulation differs from the systemic circulation: it operates at a five to tenfold lower pressure, and the vessels are shorter and wider. There are two important consequences of the particularly low vascular resistance. First, the downstream blood flow in the pulmonary capillaries is pulsatile, in contrast to the more constant systemic capillary flow.[53] Second, the capillary and alveolar walls are protected from exposure to high hydrostatic pressures; therefore, they can be sufficiently thin to optimize diffusion (i.e., exchange) of gas but not permit leakage of plasma or blood into the airspace. Whereas an abrupt increase in the pulmonary arterial (or venous) pressure can cause breaks in the capillaries,[54] slower increases (i.e., months to years) stimulate vascular remodeling.[55] This remodeling might protect against pulmonary edema[56] (and possibly against lung injury[57]), but diffusion will be impaired.

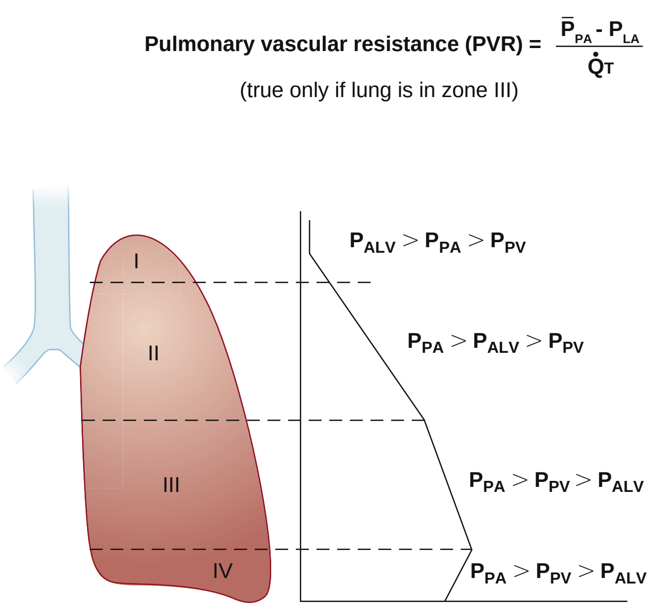
DISTRIBUTION OF LUNG BLOOD FLOW

Pulmonary blood flow depends on driving pressure and vascular resistance; these factors (and flow) are not homogenous throughout the lung. The traditional thinking about lung perfusion emphasized the importance of gravity;[58] however, factors other than gravity are also important.

DISTRIBUTION OF BLOOD FLOW IN THE LUNG: THE EFFECT OF GRAVITY

Blood has weight and therefore blood pressure is affected by gravity. The height (base to apex) of an adult lung is approximately 25 cm; therefore, when a person is standing, the hydrostatic pressure at the base is 25 cm H_2O (i.e., approximately 18 mm Hg) higher than at the apex. The mean pulmonary arterial pressure is approximately 12 mm Hg at the level of the heart, and the pulmonary artery pressure at the lung apex can therefore approach zero. Thus less blood flow will occur at the apex (versus the base), and in the setting of positive pressure ventilation, the apical alveoli can compress the surrounding capillaries and prevent any local blood flow.

Based on such gravitational distribution of pulmonary artery pressure, as well as the effect of alveolar expansion, West and colleagues[59] divided the lung into zones I to III (Fig. 13.10). This system is based on the principle that perfusion to an alveolus depends on the pressures in the pulmonary artery (P_{PA}), pulmonary vein (P_{PV}), and alveolus (P_{ALV}). In the apex (zone I), the key issue is that pulmonary arterial pressure is less than alveolar pressure; therefore, no perfusion occurs. Zone I conditions can exist during mechanical ventilation and be exacerbated by low P_{PA}. Whenever zone I conditions exist, the nonperfused alveoli constitute additional dead space (V_D). Below the apex in zone II, P_{PV} is less than alveolar pressure, and the veins are collapsed except during flow, as in a “vascular waterfall.” Although P_{ALV} is always greater than P_{PV}, perfusion occurs when P_{PA} exceeds P_{ALV} (i.e., intermittently, during systole). Below this zone is zone III, in which there are two important differences: P_{PA} and P_{PV} both always exceed P_{ALV}. As a result, there is perfusion throughout systole and diastole (and inspiration and expiration). Gravity results in equal increases in both P_{PA} and P_{PV} toward the lung base; therefore, gravity cannot affect flow throughout zone III by increasing the P_{PA} to P_{PV} pressure gradient alone. Nonetheless, it is possible that the greater weight of the blood nearer the base results in vessel dilatation, thereby lowering vascular resistance and increasing flow.[58] It was subsequently recognized that there is also a decrease in perfusion in the lung base, or zone IV, that is thought to occur because of the effects of gravity compressing the lung at the bases—and the blood vessels therein—and thereby increasing vascular resistance.[60]



Pulmonary vascular resistance (PVR) = $\frac{\bar{P}_{PA} - P_{LA}}{\dot{Q}_T}$

$P_{ALV} > P_{PA} > P_{PV}$
$P_{PA} > P_{ALV} > P_{PV}$
$P_{PA} > P_{PV} > P_{ALV}$
$P_{PA} > P_{PV} > P_{ALV}$

Fig. 13.10 Vertical distribution of lung blood flow. The so-called zones I, II, III, and IV are indicated. In zone I there is no perfusion, only ventilation. In zone II, pulmonary artery pressure exceeds alveolar pressure which in turn exceeds venous pressure; the driving pressure is $P_{PA}–P_{ALV}$. In zone III, arterial and venous pressures both exceed alveolar pressure, and here the driving pressure is $P_{PA}–P_{PV}$. In the lung base, blood flow is decreased possibly because of increased interstitial pressure that compresses extra alveolar vessels. P_{ALV}, intraalveolar pressure; P_{PV}, pulmonary vein pressure; P_{PA}, pulmonary artery pressure; Q_T, cardiac output.

Finally, additional evidence for the effect of gravity comes from volunteer experiments in which gravity was increased or abolished by altering the flight pattern of a jet aircraft.[61] In these experiments, zero gravity decreased cardiac oscillations of O_2 and CO_2 during a breath-hold, indicating development of more homogeneous perfusion. In contrast, more recent experiments of exhaled gas analysis (on the Mir space station) reported that the heterogeneity of lung perfusion was reduced, but not eliminated, in the presence of

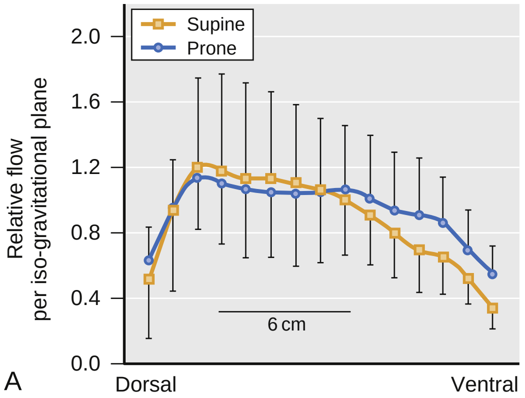

Fig. 13.11 Distribution of blood flow (ventral, dorsal) in supine versus prone position. The distributions from ventral to dorsal are similar, irrespective of position, suggesting that the anatomic features (and not simply gravity) determine the distribution of flow. The magnitude of the variability in either the prone (or in the supine) position (i.e., nongravitational inhomogeneity) is far greater than the differences in distribution between the prone and the supine positions (i.e., gravitational inhomogeneity). (From Glenny RW, Lamm WJ, Albert RK, Robertson HT. Gravity is a minor determinant of pulmonary blood flow distribution. *J Appl Physiol.* 1991;71:620–629.)

microgravity, indicating that gravity contributes to the heterogeneity of blood flow distribution but does not explain it entirely.[62] While the precise role of gravity is disputed, it is likely to play a smaller role when supine versus when upright.

DISTRIBUTION OF BLOOD FLOW IN THE LUNG: INFLUENCE OF FACTORS NOT RELATED TO GRAVITY

Key experiments have reconsidered the effects of gravity. Blood flow measured in the same gravitational plane was less per unit of lung tissue at the apex than at the base.[63] In addition, microsphere assessment demonstrated significant variability within iso-gravitational planes, and lung height appeared to account for less than 10% of the distribution of flow in either the prone or supine positions.[64] In addition, inhomogeneity in the horizontal planes can exceed that in the vertical direction (Fig. 13.11).[65] Other studies have reported a preponderance of perfusion to the central lung (versus peripheral) tissue,[66] which can be reversed by the application of positive end-expiratory pressure (PEEP).[67] Although greater length of radial blood vessels was considered to explain this central-peripheral difference, others have suggested that it is not significant.[64] Finally, differences have been reported among lung regions in local vascular resistance.[68]

Fractal distribution of blood flow may be more important than the influence of gravity.[69] A fractal pattern of perfusion means that in any given region, there will be “spatial correlation” (similarity) of the blood flow between neighboring regions.

Although the methods to study lung perfusion are complex—and there is a spectrum of opinion[70]—the aggregate data suggest that factors other than gravity contribute to the heterogeneity of the distribution of perfusion.

HYPOXIC PULMONARY VASOCONSTRICTION

HPV is a compensatory mechanism that diverts blood flow away from hypoxic lung regions toward better oxygenated regions.[71] The major stimulus for HPV is low alveolar oxygen tension (P_AO_2), whether caused by hypoventilation or by breathing gas with a low PO_2, and is more potent when affecting a smaller lung region. The stimulus of hypoxic mixed venous blood is weaker.[72,73] Whereas in humans older volatile anesthetics were thought to inhibit HPV more than intravenously based anesthesia, modern volatile anesthetics, including sevoflurane[74] and desflurane,[75] have little effect. During intravenously based anesthesia, exposure of one lung to an FiO_2 of 1.0 and the contralateral lung to a hypoxic gas mixture (FiO_2, 0.12 to 0.05) reduced perfusion to the hypoxic lung to 30% of the cardiac output.[76] Pulmonary hypertension, because of vascular remodeling owing to ongoing HPV, can develop in humans at high altitude[77] or in the presence of chronic hypoxemic lung disease.

Clinical Assessment of Lung Function

SPIROMETRY—TOTAL LUNG CAPACITY AND SUBDIVISIONS

The gas volume in the lung after a maximum inspiration is called the *total lung capacity* (TLC; usually 6 to 8 L). TLC can be increased in COPD either by overexpansion of alveoli or by destruction of the alveolar wall, resulting in loss of elastic tissue, as in emphysema (see Fig. 13.4).[78] In extreme cases, TLC can be increased to 10 to 12 L. In restrictive lung disease, TLC is reduced, reflecting the degree of fibrosis, and can be as low as 3 to 4 L (see Fig. 13.4).[78]

Following maximum expiratory effort, some air is left in the lung and constitutes the RV (approximately 2 L). However, usually no region develops collapse because distal airways (<2 mm) close before alveoli collapse,[79] trapping gas and preventing further alveolar emptying. In addition, there is a limit to how much the chest wall, rib cage, and diaphragm can be compressed. The importance of preventing collapse of lung tissue was presented earlier (see Fig. 13.6).

The maximum volume that can be inhaled and then exhaled is the vital capacity (VC; 4-6 L), and this is the difference between TLC and RV. VC is reduced in both restrictive and obstructive lung disease. In restriction, VC reduction reflects the loss of lung volume, such as from the constricting (i.e., shrinking) effects of fibrosis. In obstructive lung disease, long-term trapping of air increases the RV and can occur either by encroaching on (and reducing) the VC or in association with a (proportionally smaller) increase in FVC.[78]

Tidal volume (V_T, usually 0.5 L) is inspired from the resting lung volume reached at end-expiration (FRC, 2.0 L). With increased ventilation, as in exercise, V_T is increased and FRC may be reduced by approximately 0.5 L. However, in airway obstruction, exhalation is impeded such that inspiration commences before the usual resting lung volume is reached; thus end-expiratory volume is increased.[78] Such air trapping reduces the resistance to gas flow in the narrowed airways, but because the lung tissue is hyperinflated and mechanically disadvantaged, the work of breathing overall is increased.

FRC increases with age as elastic lung tissue is lost; this reduces the lung recoil force countering the outward chest wall force, and the lung assumes a higher volume. The rate of this aging process is accelerated in COPD because of the contributions of chronic air trapping and marked loss of elastic tissue.[19] FRC is reduced in fibrotic lung diseases,[78] sometimes to 1.5 L (see Fig. 13.4). Lung resection also reduces FRC, but the remaining lung will expand to fill the lung tissue void partially; this is called *compensatory emphysema* (see Chapter 53).

DIFFUSING CAPACITY (DL_{CO})—DIFFUSION ACROSS ALVEOLAR-CAPILLARY MEMBRANES

The diffusing capacity for carbon monoxide (DL_{CO}) test integrates many phenomena that are central to respiratory physiology. The test and the factors affecting its interpretation are described here. In the lungs, O_2 and CO_2 diffuse passively: O_2 from alveolar gas into plasma and red cells, where it binds to hemoglobin, and CO_2 in the opposite direction, from plasma to the alveoli. The amount that can diffuse across a membrane in a given period is the diffusing capacity, and it is determined with the following equation:

$$Diffusing\ capacity = \frac{(SA \times \Delta P \times Sol)}{(h \times \sqrt{MW})}$$

where SA is the surface area of the membrane exposed to gas, ΔP is the gradient of partial pressure between administered gas versus blood tension, Sol is the solubility of the gas in the membrane, h is the thickness of the membrane, and MW is the molecular weight of the gas.

Assessment of diffusing capacity (sometimes called *transfer factor*) uses CO as the test gas; it is inhaled at a small concentration (0.3%) to TLC just after a maximal expiration, filling the lung as much as possible with the dilute CO. The breath is held and then deeply exhaled to RV. The difference between the quantity of CO exhaled versus inhaled will therefore either be taken up by the perfusing blood (i.e., hemoglobin) or remain in the lung (RV). The latter can be determined if the CO is coadministered with an insoluble gas (e.g., helium) that remains in the lung.

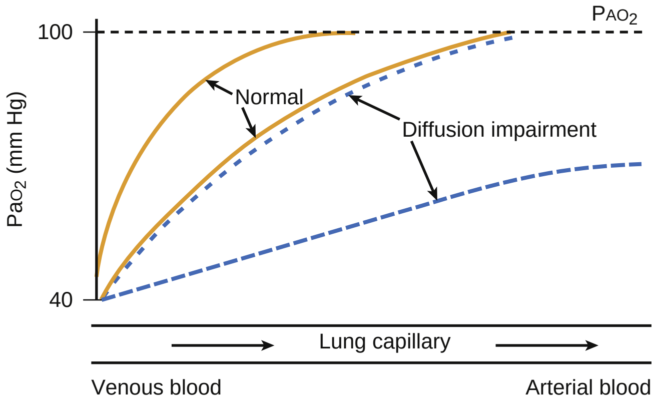

Fig. 13.12 Schematic of oxygenation of pulmonary capillary blood. In a healthy subject, there is a rapid equilibration (<30% capillary length) of the oxygen tension in capillary blood than that in alveolar gas; however, during exercise, the flow rate is greater (i.e., transit time shorter) and most of the capillary distance is used before equilibration is reached. This effect can be offset by distention and recruitment of pulmonary capillaries. If diffusion is impaired, equilibration takes longer, and it might not occur with exercise.

Surface Area

The surface area is taken as the area that is capable of exchanging gas on the alveolar and the capillary sides; thus it assumes a ventilated and perfused lung (i.e., not dead space). It will be lower in small lungs, lung fibrosis (restriction), after lung resection, or in cases of lung tissue destruction, such as emphysema.

Membrane Thickness

Thicker membranes reduce the CO transfer because the longer diffusion distance lowers the diffusion capacity, and the solubility of O_2 (and CO_2) is lower in fibrotic tissue than in plasma. Differentiating between effects of the volume of capillary blood and the membrane thickness can be difficult, but because oxygen and CO compete for binding to hemoglobin, distinguishing between these issues may be possible by measuring CO transfer with altered FiO_2 (see review by Hughes and colleagues).[80,81]

Pressure Gradient

The larger the O_2 or CO_2 tension difference (ΔP) between the gas phase (alveolus) and the plasma (capillary), the greater the rate of diffusion. The mixed venous blood entering the pulmonary capillary has a PO_2 of 40 mm Hg (5.3 kPa), and alveolar PO_2 is approximately 100 mm Hg (13.3 kPa); therefore, the driving pressure (ΔP) is 60 mm Hg (8 kPa).

When blood flows through the capillary, it takes up oxygen and delivers CO_2, but because oxygen pressure builds up in capillary blood, the diffusion rate slows down and becomes zero when pressure is equilibrated across the alveolar-capillary wall. At rest, equilibrium is usually reached within 25% to 30% of the capillary length, and almost no gas transfer occurs in the remaining capillary (Fig. 13.12). However, during exercise or stress (i.e., high cardiac output), blood flow through the capillary is faster, and a longer capillary distance is required before equilibrium is reached. Thickened alveolar-capillary membranes will also prolong the equilibration process and, if severe, can prevent equilibration occurring and increasing the propensity to hypoxemia. If the mixed venous PO_2 ($P_{mv}O_2$) is lower than normal, the driving pressure increases and partially compensates toward achieving equilibrium with alveolar O_2. The driving pressure is expressed:

$$\Delta P = (PaO_2 - P_{mv}O_2)\ mm\ Hg$$

Most of the oxygen that dissolves in plasma diffuses into the red cell and binds to hemoglobin; therefore, 1 L of blood (Hb 150 g/L) with a saturation of 98%—normal in arterial blood—carries 200 mL of Hb-bound O_2, compared with 3 mL that is dissolved (PaO_2 100 mm Hg). The Hb-bound oxygen creates no pressure in plasma, which is important because it allows much more oxygen to diffuse over the membranes before a pressure equilibration is reached. Anemia (or prior CO exposure) reduces—and polycythemia increases—diffusion capacity.

Molecular Weight and Solubility

The rate of diffusion of a gas is inversely related to the square root of its MW; the larger the molecule, the slower the diffusion. O_2 is a light gas (MW 32), and CO_2 is heavier (MW 44). However, diffusion is also directly proportional to solubility in tissue, and CO_2 is almost 30-fold more soluble than O_2. The aggregate effect is that CO_2 diffuses about 20-fold faster than O_2[82]; therefore, there is no lung disease compatible with life that measurably impairs CO_2 diffusion.

Intraoperative Respiratory Events

RESPIRATORY FUNCTION DURING ANESTHESIA

Anesthesia impairs pulmonary function, whether the patient is breathing spontaneously or is receiving mechanical ventilation. Impaired oxygenation of blood occurs in most subjects who are anesthetized,[83] and this is why supplemental O_2 (FiO_2 usually 0.3-0.5) is almost invariably used. Mild to moderate hypoxemia (SaO_2, 85% to 90%) is common and lasts from seconds to minutes; sometimes it is severe, and approximately 20% of patients may suffer from SaO_2 less than 81% for up to 5 minutes.[84] Indeed, greater than 50% of claims in anesthesia-related deaths relate to hypoxemia during anesthesia.[2] Beyond the operating room, the alterations in lung function acquired during anesthesia persist: clinically significant pulmonary complications can be seen in 1% to 2% of patients after minor surgery, and in up to 20% of patients after more major upper abdominal or thoracic surgery.[85] Such consequences of anesthesia place prime importance on ascertaining the causes of perioperative respiratory dysfunction and the clinical approaches to treatment.

In this section, we describe the effects of anesthesia and mechanical ventilation on lung function. The arrangement of this section parallels the sequence of events involved in oxygenating the blood and removing CO_2. Thus the first phenomenon that might be seen with anesthesia is loss of muscle tone with a subsequent change in the balance between outward forces (i.e., respiratory muscles) and inward forces (i.e., elastic tissue in the lung) leading to a fall in FRC. This causes or is paralleled by an increase in the elastic behavior of the lung (reduced compliance) and an increase in respiratory resistance. The decrease in FRC affects the patency of lung tissue with the formation of atelectasis (made worse with the use of high concentrations of inspired oxygen) and airway closure. This alters the distribution of ventilation and matching of ventilation and blood flow and impedes oxygenation of blood and removal of CO_2.

LUNG VOLUME AND RESPIRATORY MECHANICS DURING ANESTHESIA

Lung Volume

Resting lung volume (i.e., FRC) is reduced by almost 1 L by moving from upright to supine position; induction of anesthesia further decreases the FRC by approximately 0.5 L.[86] This reduces the FRC from approximately 3.5 to 2 L, a value close to RV. General anesthesia causes a fall in FRC (approximately 20%), whether breathing is controlled or spontaneous[87,88] and whether the anesthetic is inhalational or intravenous;[89] this is a major contributor to lowered oxygenation (discussed later). Muscle paralysis in the context of general anesthesia does not cause additional reduction in FRC.

The anatomic basis of the FRC reduction is not well understood. A landmark experiment on three volunteers using two-dimensional tomography suggested that a cephalad shift of the diaphragm, induced by anesthesia and paralysis, was responsible.[90] Recent studies using CT scanning also suggest cephalad diaphragm shift, as well as a decrease in the transverse chest area.[89,91] However, other data suggest little role for the diaphragm, with possible caudal (not cephalad) shift of its anterior aspect.[92] Simple CT suggests a cranial displacement, except in severe obstructive lung disease. Although the anatomic components of reduced FRC are debatable, the mechanism appears to be related to loss of respiratory muscle tone. FRC is maintained by a balance of the forces inward (lung recoil) versus forces outward (chest wall recoil, chest wall muscles, diaphragm). For example, maintenance of muscle tone using ketamine as the anesthetic does not reduce FRC.[89] Because patients are usually supine, the FRC will already have been reduced, and in elderly patients, this is particularly the case; in this context, the effects of anesthesia are more marked (see Fig. 13.9). As can be seen in the figure, FRC decreases with age assuming that weight does not change.

Compliance and Resistance of the Respiratory System

Static compliance of the total respiratory system (lungs and chest wall) is reduced on average from 95 to 60 mL/cm H_2O during anesthesia.[93] Most studies of lung compliance during anesthesia indicate a decrease compared with the awake state, and pooled data from several studies suggest that anesthesia is associated with a reduction in mean static compliance from almost 190 to approximately 150 mL/cm H_2O.[93] Data on changes in respiratory resistance are less clear. Although most studies suggest that anesthesia increases respiratory resistance, especially during mechanical ventilation,[93] no studies have corrected for lung volume and flow rates (both affect resistance considerably), and it is possible that changes in resistance occur merely because of volume (i.e., FRC) loss (Fig. 13.13).

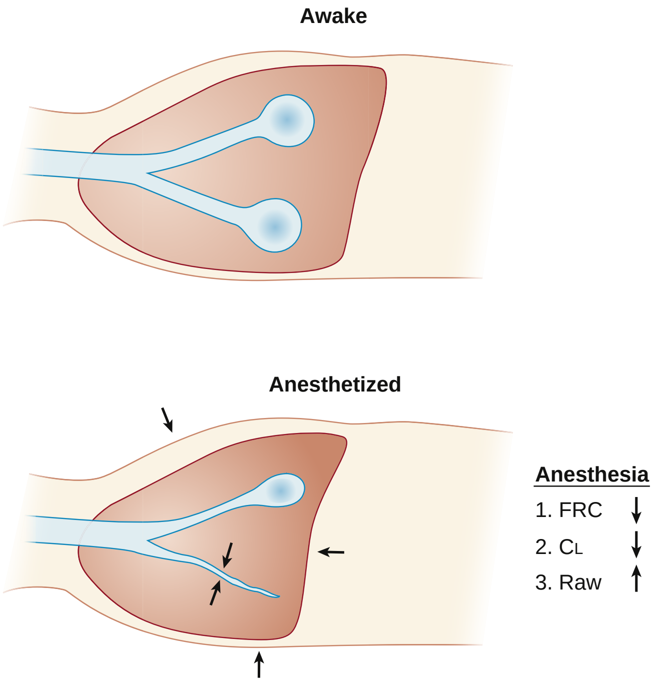

Fig. 13.13 Anesthesia induces cranial shift of the diaphragm and a decrease of transverse diameter of the thorax. These effects contribute to a lowered functional residual capacity *(FRC)*. The decreased ventilated volume (atelectasis and airway closure) can contribute to reduced compliance *(C_L)*. Decreased airway dimensions by the lowered FRC can contribute to increased airway resistance (Raw).

ATELECTASIS AND AIRWAY CLOSURE DURING ANESTHESIA

The classic article by Bendixen and colleagues[94] proposed "a concept of atelectasis" as a cause of impaired oxygenation and reduced respiratory compliance during anesthesia.[94] That study described a progressive decrease in compliance that paralleled decreases in oxygenation in both anesthetized humans and experimental animals, which was interpreted as progressive of atelectasis. However, others noticed an abrupt decrease in compliance and PaO_2 during induction of anesthesia, and yet atelectasis could not be shown on conventional chest radiography.

Since then, CT scanning has improved our knowledge of the nature of anesthesia-induced atelectasis, and the technique reveals prompt development of densities in the dependent regions of both lungs during anesthesia (data up to 1990 reviewed by Moller and associates).[84,95] Morphologic studies of these densities in various animals supported the diagnosis of atelectasis. An example of atelectasis as seen on a CT scan is shown in Fig. 13.14.

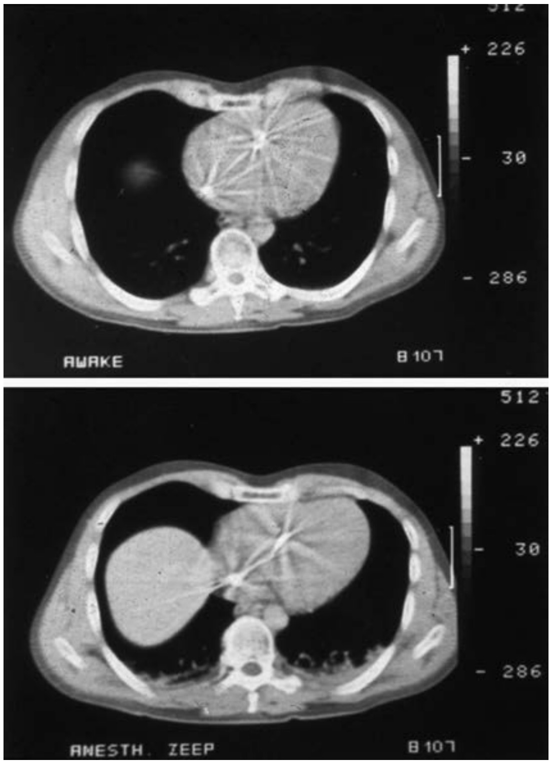

Fig. 13.14 Computed tomography with transverse exposures of the chest when the subject is awake *(upper panel)* and anesthetized *(lower panel)*. In the awake condition, the lung is well aerated (radiations from a pulmonary artery catheter are seen in the heart). During anesthesia, atelectasis has developed in the dependent regions *(grey/white irregular areas)*. The large grey/white area in the middle of the right lung field is caused by a cranial shift of the diaphragm and the underlying liver.

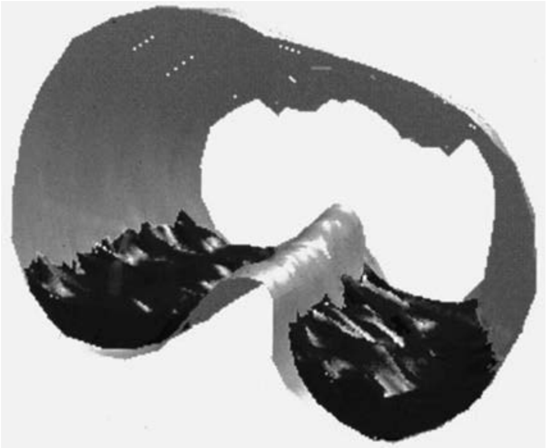

Fig. 13.15 A three-dimensional reconstruction of the thorax of an anesthetized patient with atelectasis in the dependent regions of both lungs. There is a slight decrease in the degree of atelectasis toward the apex (distal in this image). (Data from Reber A, Nylund U, Hedenstierna G. Position and shape of the diaphragm: implications for atelectasis formation. *Anaesthesia*. 1998;53:1054–1061.)

Atelectasis develops in approximately 90% of patients who are anesthetized, but it is unrelated to the choice of anesthesia.[96] It is seen during spontaneous breathing and after muscle paralysis, and with either intravenous or inhaled anesthetics.[89] The atelectatic area near the diaphragm is usually 5% to 6% of the total lung area, but can easily exceed 20%. The amount of lung tissue that is collapsed is larger, because the atelectatic area consists mostly of lung tissue, whereas normal aerated lung consists of 20% to 40% tissue (the rest being air). Thus 15% to 20% of the lung is atelectatic during uneventful anesthesia, before surgery has commenced; it decreases toward the apex, which usually remains aerated (Fig. 13.15). However, this degree of atelectasis is larger (upward of 50% of lung volume) after thoracic surgery or cardiopulmonary bypass, and can last for several hours.[97] Abdominal surgery adds little to the atelectasis, but after such surgery, it can persist for several days.[98]

CT scan and vertical distribution of ventilation and perfusion
in the same lung segment

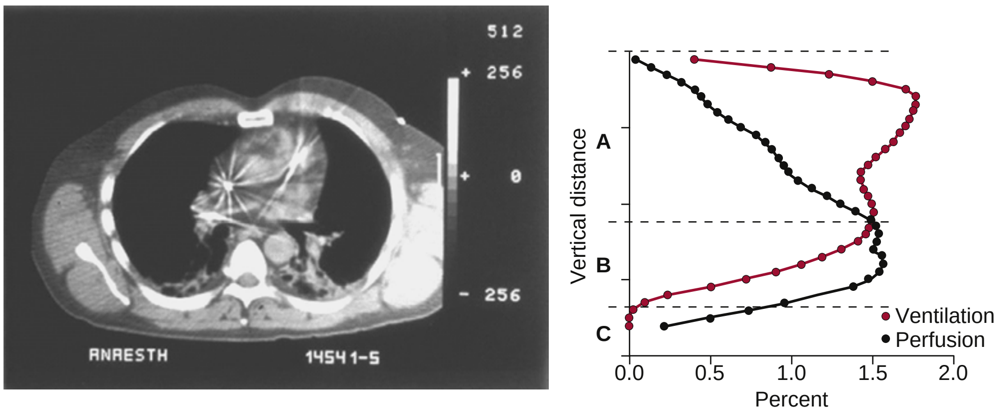

Fig. 13.16 Atelectasis and distribution of ventilation and blood flow. The *left panel* is a cross-sectional slice of a computed tomographic image of the chest of an anesthetized patient, illustrating atelectasis in the basal (dorsal) regions. The *right panel* illustrates the distribution of ventilation and perfusion throughout that slice. The bulk of the ventilation is to the upper lung region (zone *A*), in contrast to the awake subject without atelectasis, and it exceeds the level of local perfusion; this results in wasted ventilation (i.e., dead space) in the upper regions. In the lower region (zone *B*), the ventilation is less (probably because of intermittent airway closure) and is exceeded by the local perfusion, resulting in areas of low $\dot{V}_A/Q$, causing hypoxemia. In the next lowest region (zone *C*), there is complete cessation of ventilation because of atelectasis, but some perfusion exists and causes a shunt. The farther from the top of the lung, the higher the perfusion; however, in the lowermost regions perfusion decreases (see text). (Data from Hedenstierna G. Alveolar collapse and closure of airways: regular effects of anaesthesia. *Clin Physiol Funct Imaging.* 2003;23:123–129.)

Atelectasis is an important cause of hypoxemia: there is a strong and significant correlation between the degree of atelectasis and the size of the pulmonary shunt (R = 0.81), where atelectasis is expressed as the percentage of lung area just above the diaphragm on CT scan and shunt is expressed as the percentage of cardiac output using the multiple inert gas elimination technique (MIGET).[96] The site of the increased shunt has been colocalized to the areas of atelectasis, using a technique that combines CT scanning and single photon emission computed tomography (SPECT; Fig. 13.16).[99] In addition to shunt, atelectasis may form a focus of infection and can certainly contribute to pulmonary complications.[100]

Aside from anesthesia (and the type of surgery), it is difficult to predict the development of atelectasis. The magnitude of atelectasis is often directly related to the body mass index (BMI) and inspired oxygen concentration.[87,89] Moreover, neither age[96] nor the presence of COPD[101] predicts the development or extent of atelectasis. In COPD, it may be that airway closure precedes (and therefore prevents) alveolar closure. Alternatively, the greater loss of lung (elastic recoil) versus chest wall tissue may serve to protect against atelectasis.

PREVENTION OF ATELECTASIS DURING ANESTHESIA

Several interventions can help prevent atelectasis[95] or even reopen collapsed tissue, as discussed in the following sections.

Positive End-Expiratory Pressure

The application of PEEP (10 cm H_2O) has been repeatedly demonstrated to reexpand atelectasis in part (Fig. 13.17). Some atelectasis may persist and might require higher PEEP and inspiratory airway pressure.[89] The application of larger levels of PEEP can have complex effects. Reversal of hypoxemia is not proportionally associated with applied PEEP, and a threshold exists in many cases. In addition, SaO_2 may decrease during the application of increased PEEP for two reasons. First, the increased P_{PL} owing to the PEEP can impair venous return, especially in the presence of hypovolemia, lowering the cardiac output and oxygen delivery (DO_2) and thereby reducing mixed venous O_2 content (C_vO_2). In the presence of an intrapulmonary shunt, such as with atelectasis, the mixed venous blood is shunted directly into pulmonary venous blood causing arterial desaturation. Second, increased PEEP can cause redistribution of blood flow away from the aerated, expanded regions (distended by PEEP) toward atelectatic areas (not distended by PEEP; Fig. 13.18).[102] In this context, persisting atelectasis in a dependent lung receives a larger proportion of the total pulmonary blood flow than without PEEP.[58] Finally, anesthesia-induced atelectasis rapidly reemerges after discontinuation of PEEP.[89] Indeed, Hewlett and coworkers[103] in 1974 cautioned against the "indiscriminate use of PEEP in routine anesthesia."

To avoid negative circulatory effects, the magnitude of PEEP should just be enough to open up a collapsed lung. A PEEP of 7 cm H_2O in normal-weight patients (BMI < 25 kg/m^2) without cardiopulmonary disease will recruit most of the lung, and keep it open with better oxygenation than in a comparable group without PEEP.[104] Thus a forceful dedicated recruit maneuver should not be needed. This effect was seen in nonabdominal surgery, and whether similar beneficial effect will be seen in abdominal surgery remains to be shown.

Recruitment Maneuvers

A sigh maneuver, or a large V_T, has been suggested for reversing atelectasis[10]; however, atelectasis is not uniformly reduced by a V_T increase or sigh up to P_{AW} of 20 cm H_2O.[105] Instead, a P_{AW} of 30 cm H_2O is required for initial opening, and 40 cm H_2O for more complete reversal (Fig. 13.19). In the presence of normal lungs, such inflation is equivalent to a VC and can therefore be called a *VC*

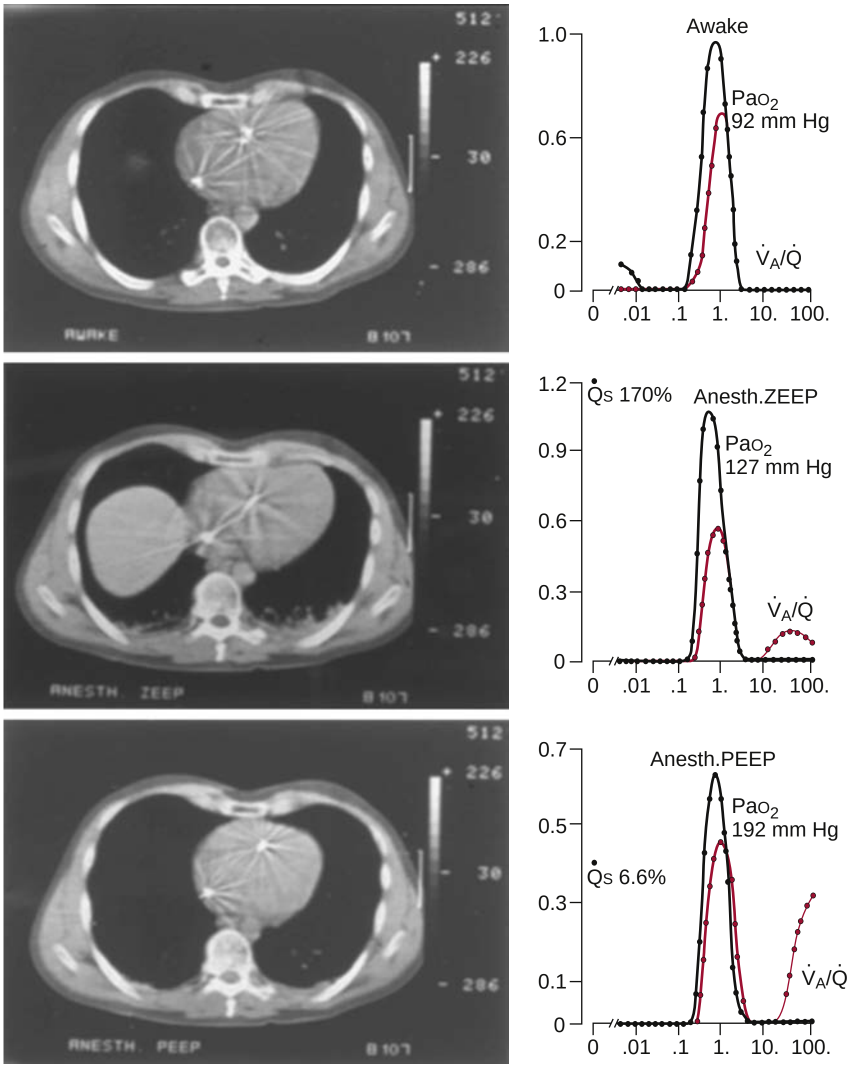

Fig. 13.17 Computed tomographic scans and $\dot{V}_A/\dot{Q}$ distributions in the lung of a healthy, awake subject during anesthesia (zero positive end-expiratory pressure *[ZEEP]*) and during anesthesia (10 cm H_2O positive end-expiratory pressure *[PEEP]*). In the awake state, there is no atelectasis and the corresponding minor low $\dot{V}_A/\dot{Q}$ distribution (*left side* of plot) may reflect intermittent airway closure. During anesthesia with ZEEP, atelectasis is apparent in the lung bases (and the diaphragm has been pushed cranially). The low $\dot{V}_A/\dot{Q}$ has been replaced by atelectasis and large shunt; in addition, a small "high" $\dot{V}_A/\dot{Q}$ mode (*right side* of plot) may reflect alveolar dead space in upper lung regions. With the addition of PEEP during anesthesia, the collapsed lung tissue has been recruited and the shunt has been reduced considerably. Moreover, the "high" $\dot{V}_A/\dot{Q}$ mode (*right side* of plot) has significantly increased; this may reflect additional inflation of nonperfused upper lung.

maneuver (albeit achieved with positive P_{AW}). In addition, a significant hemodynamic effect is likely if the VC maneuver is sustained; in fact, inflation with a P_{AW} of 40 cm H_2O for 7 to 8 seconds appears to successfully open almost all anesthesia-induced atelectasis.[106]

Minimizing Gas Resorption

Although recruitment of anesthesia-induced atelectasis is completely possible with either PEEP or a VC maneuver, continuous application of some level of PEEP is required to prevent rapid recurrence of the atelectasis.[107] However, nitrogen (N_2)—an insoluble gas that is not absorbed into the blood—can "splint" the alveolus if the alveolus is already opened. As a result, in anesthetized patients, a VC maneuver followed by ventilation with a gas mixture containing 60% N_2 (40% O_2) reduced the propensity for reaccumulation of atelectasis, with only 20% reappearing 40 minutes after recruitment.[107]

The same principles apply in the practice of preoxygenation of patients during induction of anesthesia. Here, the aim is to prevent O_2 desaturation (i.e., gain an O_2 safety margin) during induction before the airway has been secured when the anesthesiologist can better manage ventilation and oxygenation. Traditionally, the application of FiO_2 1.0 has been used. Although the SaO_2 is usually well maintained with this approach, atelectasis inevitably forms. The use of 30% versus 100% O_2 during induction was demonstrated in a clinical study to eliminate the formation of atelectasis.[108] Later, a comparison of breathing 100%, 80%, and 60% O_2 during induction demonstrated ubiquitous atelectasis with 100%, less with 80%, and even less with 60% O_2 (Fig. 13.20); however, the trade-off for less atelectasis was a shorter safety margin before occurrence of O_2 desaturation.[109]

An alternative approach may be continuous positive airway pressure (CPAP). Application of CPAP 10 cm

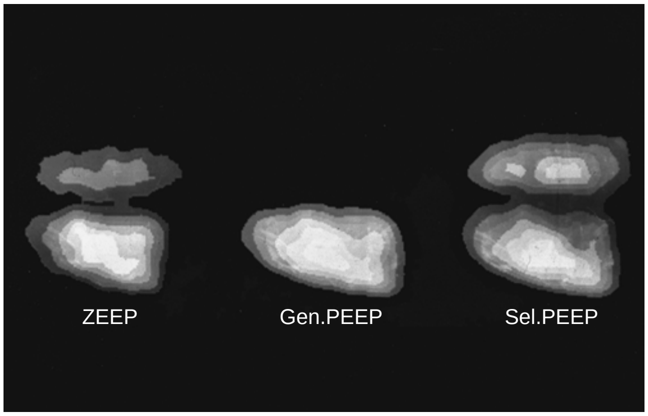

Fig. 13.18 Gamma camera images of lung blood flow in an anesthetized subject in the lateral position. During mechanical ventilation with zero end-expiratory pressure *(ZEEP)*, perfusion is predominantly (60%-70% of cardiac output) to the lower lung. Applying PEEP (10 cm H_2O) to both lungs forces more perfusion to the lower lung, leaving almost no perfusion to the upper lung (i.e., major increase in V_D). In contrast, selective application of PEEP to the lower lung causes redistribution of perfusion to the upper lung. Of course, the image presented is perfused tissue (not total anatomic lung tissue; in the right lateral position the upper-right lung would be larger). *PEEP*, Positive end-expiratory pressure. (From Hedenstierna G, Baehrendtz S, Klingstedt C, et al. Ventilation and perfusion of each lung during differential ventilation with selective PEEP. *Anesthesiology.* 1984;61:369–376.)

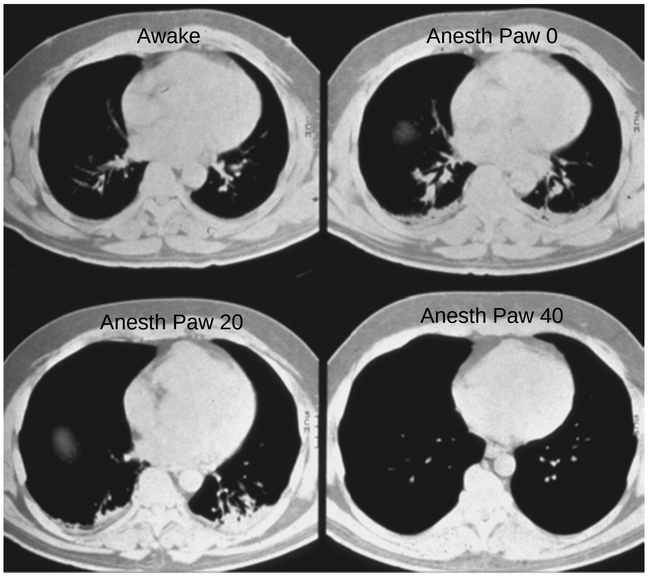

Fig. 13.19 Computed tomographic (CT) scans during awake and anesthetized states with altered airway pressure *(P_{AW})*. The CT scan in the awake subject *(upper left panel)* shows normal vasculature and no atelectasis. During anesthesia (P_{AW}, 0 cm H_2O; *upper right panel*), bilateral basal atelectasis is seen; the P_{AW} is increased in increments (20 cm H_2O shown), but the atelectasis is not reversed until a P_{AW} of 40 cm H_2O is applied (*lower right panel*). Thus a vital capacity maneuver was required to open the lung. (From Rothen HU, Sporre B, Engberg G, Wegenius G, Hedenstierna G. Re-expansion of atelectasis during general anaesthesia: a computed tomography study. *Br J Anaesth.* 1993;71:788–795.)

H_2O permitted the use of 100% inspired O_2 without formation of significant degrees of atelectasis.[110] This might provide an ideal combination of minimal risk of either O_2 desaturation or atelectasis, but it has not been repeatedly verified.

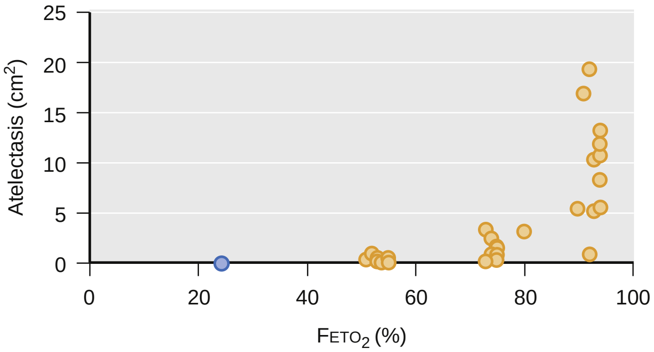

Fig. 13.20 Atelectasis formation in anesthetized subjects following preoxygenation with different inspired oxygen concentrations. Increasing the FiO_2 during preoxygenation increases the propensity to subsequent atelectasis (closed symbols), although there is much variability. The blue circle at around an expired oxygen concentration ($FETO_2$) of 25% represents data from anesthesia being induced while breathing 30% O_2. *$FETO_2$*, Expiratory oxygen fraction. (From Rothen HU, Sporre B, Engberg G, Wegenius G, Reber A, Hedenstierna G. Prevention of atelectasis during general anaesthesia. *Lancet.* 1995;345:1387–1391.)

Maintenance of Muscle Tone

Because loss of muscle tone in the diaphragm or chest wall appears to increase the risk of atelectasis, techniques that preserve muscle tone may have advantages. Intravenous ketamine does not impair muscle tone and is the only individual anesthetic that does not cause atelectasis. If neuromuscular blockade is added, atelectasis occurs as with other anesthetics.[90] Ketamine is an extremely useful anesthetic in special circumstances but has challenges with widespread use.

An experimental approach is restoration of respiratory muscle tone by diaphragm pacing. This approach is achieved with phrenic nerve stimulation, and it can modestly reduce the degree of atelectasis; however, the effect is minor and the approach is complicated.[111]

Atelectasis Following Surgery

Hypoxemia is common after anesthesia and surgery. It is enhanced by breathing oxygen before induction of anesthesia and suctioning of the airway (negative pressure) before extubation of the trachea. In addition, splinting and inhibition of coughing associated with pain can cause atelectasis postoperatively. Several approaches have been tried to address such atelectasis-associated hypoxemia following surgery. Administration of 100% O_2 coupled with a VC maneuver is not effective; this is probably because while the VC maneuver recruits the lung, the alveolar opening is not maintained (in fact closure is encouraged by the N_2-free O_2).[111] However, a VC maneuver followed by a lower O_2 concentration (40% O_2 in N_2) can maintain an open lung until the end of anesthesia.[106] Oxygenation is sustained for a longer period following ventilation with 50% O_2 in air (i.e., N_2) compared with 100%, following cardiopulmonary bypass.[113] In addition, use of 100% inspired oxygen before extubation increases the propensity to atelectasis[112] and treatment of postoperative hypoxemia, considered to be due to atelectasis, is associated with better outcomes when CPAP is used instead of 100% O_2.[114]

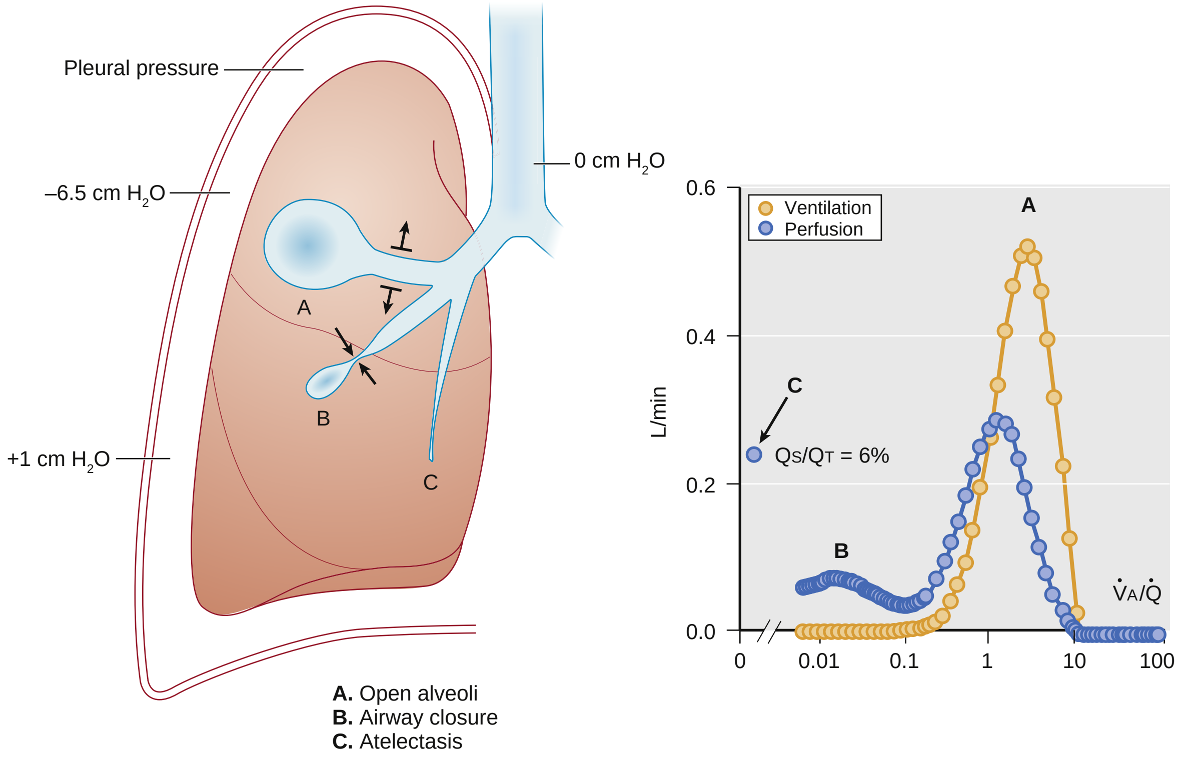

Fig. 13.21 A three-compartment model of ventilation and perfusion during anesthesia. In the upper regions, the alveoli and airways are open *(left panel, A)*. In the middle region, the airways are intermittently closed *(B)*, and atelectasis is present in the lower region *(C)*. The corresponding ventilation-perfusion distribution (multiple inert gas elimination technique) is illustrated in the *right panel*. Mode *A* reflects good ventilation and perfusion, whereas mode *B* reflects intermittent airway closure. In addition, there is a shunt in the atelectatic region (mode *C*). Q_S/Q_T, Venous admixture, or shunt equation.

AIRWAY CLOSURE

Intermittent airway closure reduces ventilation of the affected alveoli. Such lung regions can become regions of low $\dot{V}_A/\dot{Q}$ if perfusion is maintained or is not reduced to the same degree as ventilation. The propensity to airway closure increases with age (see Fig. 13.9),[49] as does perfusion to low $\dot{V}_A/\dot{Q}$ regions.[115] Anesthesia reduces FRC by about 0.5 L,[87] which increases airway closure during tidal ventilation.[116,117] In fact, the reduction in ventilation in the nonatelectatic lung (Fig. 13.21) is caused by airway closure. In addition, ventilation in these regions is less than perfusion (i.e., regions of low $\dot{V}_A/\dot{Q}$) and contributes to impaired oxygenation during anesthesia. Taken together, the combination of atelectasis and airway closure explain about 75% of the overall impairment in oxygenation.[88] In addition, where (CV–ERV) indicates the amount of airway closure occurring above FRC (and ERV is expiratory reserve volume), this value increased with induction of anesthesia, and there is good correlation between low $\dot{V}_A/\dot{Q}$ and the extent of airway closure.[88] In summary, a simple three-compartment lung model (normal $\dot{V}_A/\dot{Q}$ matching regions, region of airway closure, and atelectatic lung) describes well the components contributing to impairment of oxygenation during anesthesia (see Fig. 13.21).

DISTRIBUTION OF VENTILATION AND BLOOD FLOW DURING ANESTHESIA

Distribution of Ventilation

Redistribution of inspired gas away from dependent to nondependent lung regions has been demonstrated, using isotope techniques in anesthetized supine humans. Radiolabeled aerosol and SPECT demonstrate that ventilation is distributed mainly to the upper lung regions, with a successive decrease toward the lower lung regions, and an absence of ventilation in the lower-most regions, a finding consistent with the atelectasis demonstrable using CT (see Fig. 13.16).[100]

Recruitment maneuvers increase dependent lung ventilation in anesthetized subjects in the lateral[118] and supine[119] positions, restoring the distribution of ventilation to that in the awake state. Thus restoration of overall FRC toward the awake level returns gas distribution toward the awake pattern. The explanations are recruitment of atelectatic lung, reopening of closed airways, and further expansion of already expanded (upper) lung regions, decreasing regional compliance and lessening incremental ventilation.

Distribution of Lung Blood Flow

The distribution of lung blood flow has been studied by injection of radioactively labeled macroaggregated albumin and SPECT.[99] During anesthesia, a successive increase in perfusion occurs from upper toward lower regions, with a slight drop in perfusion in the lowermost portion of the lung, which is atelectatic on simultaneous CT (see Fig. 13.16). PEEP will impede venous return to the right heart and reduce cardiac output. It can also affect pulmonary vascular resistance, although this would have little effect on cardiac output. In addition, PEEP redistributes blood flow toward dependent lung regions,[59,119] reducing flow (and increasing dead space) in the upper lung; the increased dependent flow may increase shunt through atelectatic lung.[102]

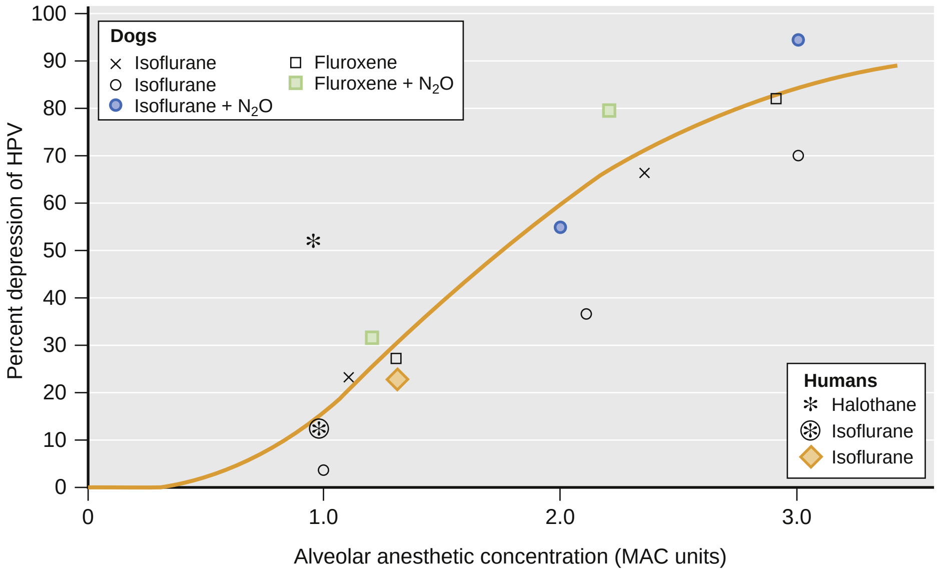

Fig. 13.22 Effect of inhaled anesthetics on hypoxic pulmonary vasoconstriction *(HPV)*. A concentration of 1 MAC causes a 20% to 30% depression of HPV, and the HPV depression decreases sharply with higher concentrations. The effect is that the shunt (i.e., perfusion through nonventilated regions) will be less reduced during inhalational anesthesia. *MAC*, Minimum alveolar concentration. (From Marshall BE. Hypoxic pulmonary vasoconstriction. *Acta Anaesthesiol Scand Suppl.* 1990;94:37–41.)

HYPOXIC PULMONARY VASOCONSTRICTION

Several inhaled—but not intravenous—anesthetics inhibit HPV in isolated lung preparations.[120] Human studies of HPV are complex with multiple parameters changing simultaneously, thereby confounding the HPV response with changes in cardiac output, myocardial contractility, vascular tone, blood volume distribution, pH, P_{CO_2}, and lung mechanics. However, studies with no obvious changes in cardiac output indicated that isoflurane and halothane depress the HPV response by 50% at a minimum alveolar concentration (MAC) of 2 (Fig. 13.22).[121]

Ventilation-Perfusion Matching During Anesthesia

DEAD SPACE, SHUNT, AND VENTILATION-PERFUSION RELATIONSHIPS

CO_2 Elimination

Anesthesia impairs CO_2 elimination and oxygenation of blood. The explanation for reduced CO_2 elimination is reduced minute ventilation ($\dot{V}_E$) because of respiratory depression, or where this is preserved, because of an increase in the V_D/V_T. Single-breath wash out recordings demonstrate that “anatomic” dead space is unchanged, indicating that increased V_D/V_T is alveolar and confirmed by MIGET scan (Fig. 13.23).[10] Such high $\dot{V}_A/\dot{Q}$ can be explained by the perfusion of small corner vessels in interalveolar septa in the upper lung regions, where alveolar pressure can exceed pulmonary vascular pressure (zone I).[84] The impaired CO_2 elimination is most easily corrected by increasing the ventilation and is seldom a problem in routine anesthesia with mechanical ventilation.

Oxygenation

The impairment in arterial oxygenation during anesthesia is more marked with increased age, obesity, and

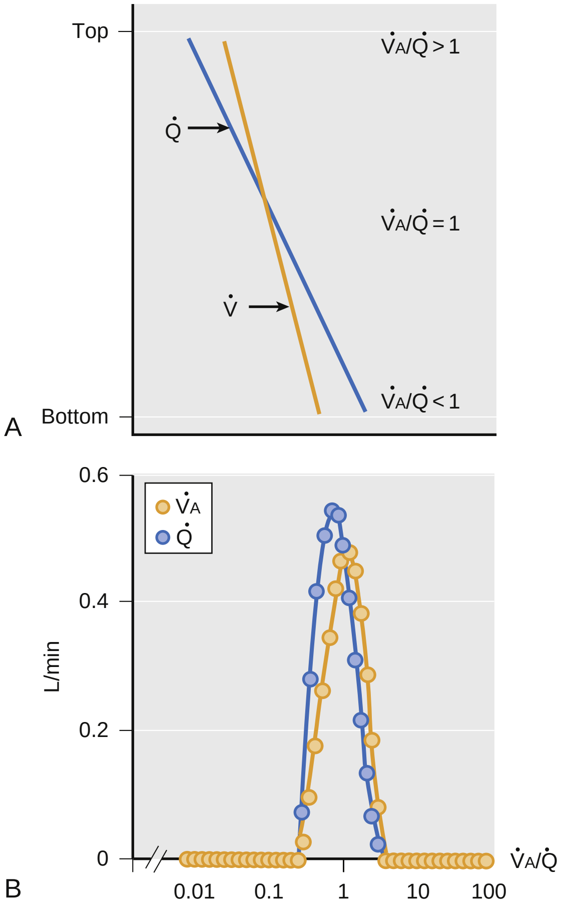

Fig. 13.23 A schematic drawing of (A) the vertical distributions of ventilation ($\dot{V}_A$) and blood flow through the lung ($\dot{Q}$) and (B) the resulting ventilation-perfusion distribution ($\dot{V}_A/\dot{Q}$). The $\dot{V}_A/\dot{Q}$ distribution is centered at a ratio of 1, corresponding to the intersection of the ventilation and perfusion distribution curves. The slightly larger ventilation than perfusion in upper lung regions contribute to the high $\dot{V}_A/\dot{Q}$ ratios greater than 1, whereas the larger perfusion than ventilation in the lower part of the lung is the cause of the lower $\dot{V}_A/\dot{Q}$ ratios, less than 1. Although there is a moderate increase in ventilation down the lung, the increase in perfusion is greater.

BOX 13.2 Derivation of the Venous Admixture (Shunt) Equation

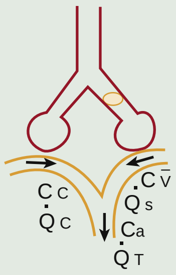
$$Ca \times \dot{Q}_T = \left(Cc' \times \dot{Q}_C\right) + \left(C_{\bar{v}} \times \dot{Q}_S\right) \qquad (1)$$

$$\dot{Q}_C = \dot{Q}_T - \dot{Q}_S \qquad (2)$$

By inserting Equation (2) (accounts for all blood flow through the lungs) into Equation (1) (accounts for all oxygen carriage through the lungs),

$$Ca \times \dot{Q}_T = \left(C_c \times \left[\dot{Q}_T - \dot{Q}_S\right]\right) + \left(C_{\bar{v}} \times \dot{Q}_S\right)$$

Rearranging,



$$\frac{\dot{Q}_S}{\dot{Q}_T} = \frac{Cc' - Ca}{Cc' - C\bar{v}}$$

where Cc′, Ca, and Cv are oxygen content in pulmonary end-capillary, arterial, and mixed venous blood, respectively; $\dot{Q}_T$ is cardiac output; $\dot{Q}_C$ is capillary flow; and $\dot{Q}_S$ is shunt.

smoking.[122,123] Venous admixture, as calculated by the standard oxygen shunt equation, is also increased during anesthesia to approximately 10% of cardiac output. However, this is an averaged calculation that considers hypoxia caused by pure shunt only, when actually it is due to a combination of "true" shunt (i.e., perfusion of nonventilated lung), poor ventilation of some regions, and regions that are ventilated but are perfused in excess of their ventilation (low $\dot{V}_A/\dot{Q}$ regions). The combination of these effects is called *venous admixture*. The shunt equation (derived in Box 13.2) assumes that all blood flow through the lung goes to either of two compartments: in one (the non–shunt fraction), all the blood is oxygenated; and in the other (the shunt fraction), all blood is shunted.

The shunt equation (or venous admixture) can be written:[124]

$$\frac{\dot{Q}_S}{\dot{Q}_T} = \frac{(C_cO_2 - C_aO_2)}{(C_cO_2 - C_{\bar{v}}O_2)}$$

Because pulmonary end-capillary blood is assumed to be maximally saturated (therefore, $S_cO_2 = 1$), the quantity of dissolved O_2 can be ignored, and it can be the difference between $C_{\dot{v}}O_2$, and $C_{\dot{v}}O_2$ can be assumed to be small ($C_vO_2 = C_{\dot{v}}O_2$):

$$\frac{\dot{Q}_S}{\dot{Q}_T} = \frac{(1 - S_ao_2)}{(1 - S_vo_2)}$$

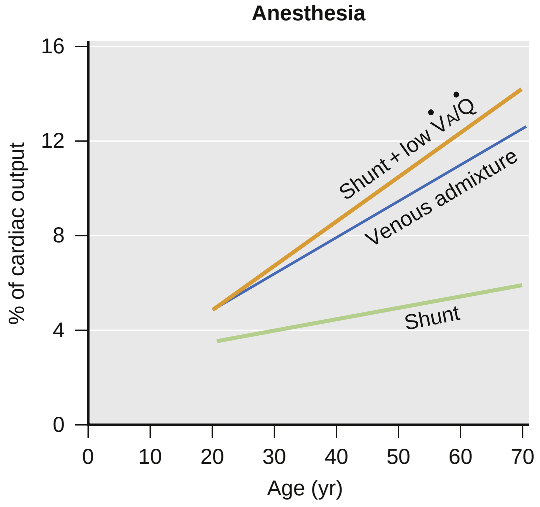


Fig. 13.24 The effect of age on oxygenation during anesthesia. The combination of shunt with low $\dot{V}_A/\dot{Q}$ increases sharply with age (as does the degree of venous admixture). The increase in shunt with age, while significant, is less striking. (From Gunnarsson L, Tokics L, Gustavsson H, Hedenstierna G. Influence of age on atelectasis formation and gas exchange impairment during general anaesthesia. *Br J Anaesth.* 1991;66:423–432.)

Thus the effect of interventions on estimated shunt can be calculated easily from the changes in SaO_2 and SvO_2.

The extent of venous admixture depends on the inspired oxygen fraction (FiO_2). The higher the inspired oxygen fraction, the less there are of the low $\dot{V}_A/\dot{Q}$ regions. However, with high FiO_2, regions with low $\dot{V}_A/\dot{Q}$ may collapse because of gas adsorption and be transformed to shunt regions.[125] A good correlation between venous admixture versus the sum of "true" shunt and perfusion of low $\dot{V}_A/\dot{Q}$ regions was seen in a study involving 45 anesthetized subjects (Fig. 13.24).[97] Derivation of the "oxygen shunt" or venous admixture is shown in Box 13.2.

In young healthy volunteers during anesthesia with thiopental and methoxyflurane, both ventilation and perfusion were distributed to wider ranges of $\dot{V}_A/\dot{Q}$ ratios, which can be expressed as an increase in the logarithmic standard deviation of the perfusion distribution (log SD$\dot{Q}$). In a similar group of patients studied during halothane anesthesia and muscle paralysis, log SD$\dot{Q}$ was almost doubled (0.43 awake, 0.80 during anesthesia). In addition, true shunt was increased to a mean of 8%. A similar increase in shunt from 1% awake to a mean of 9% during anesthesia was recorded in a study on middle-aged (37 to 64 years) surgical patients, and there was a widening of the distribution (log SD$\dot{Q}$: 0.47 awake, 1.01 during anesthesia). In older patients with more severe impairment of lung function, halothane anesthesia with muscle paralysis, with or without nitrous oxide, caused considerable widening of the $\dot{V}_A/\dot{Q}$ distribution (log SD$\dot{Q}$ 0.87 awake, 1.73 during anesthesia). In addition, shunt increased to a mean of 15%, with large variation among patients (0% to 30%). Thus the most consistent findings during anesthesia are an increased $\dot{V}_A/\dot{Q}$ mismatch, expressed as an increased log SDQ, and an increase in shunt. For review, see the article by Hedenstierna.[83]

Spontaneous ventilation is frequently reduced during anesthesia because inhaled anesthetics[126] or barbiturates[127] reduce sensitivity to CO_2. The response is dose-dependent and ventilation decreases with deepening anesthesia. Anesthesia also reduces the response to hypoxia, possibly because of effects on the carotid body chemoreceptors.[128]

The effects of anesthesia on respiratory muscle function are becoming better understood.[129] The effects are not uniform. Rib cage excursions diminish with deepening anesthesia.[130] The predominant ventilatory response to CO_2 is produced by the intercostal muscles,[131, 132] but with no clear increase in rib cage motion with CO_2 rebreathing during halothane anesthesia. Thus the reduced ventilatory response to CO_2 during anesthesia is due to impeded function of the intercostal muscles.

Factors that Influence Respiratory Function During Anesthesia

SPONTANEOUS BREATHING

Most studies of lung function have been performed on anesthetized, mechanically ventilated subjects or animals. Spontaneous breathing has been studied rarely. FRC decreases to the same extent during anesthesia, regardless of whether a muscle relaxant is used,[90,91] and atelectasis occurs to almost the same extent in anesthetized, spontaneously breathing subjects as during muscle paralysis.[133] Furthermore, the cranial shift of the diaphragm, as reported by Froese and Bryan,[90] was of the same magnitude both during general anesthesia with spontaneous breathing and with muscle paralysis, even though a difference in movement of the diaphragm from the resting position was noted. Thus, during spontaneous breathing, the lower, dependent portion of the diaphragm moved the most, whereas with muscle paralysis, the upper, nondependent part showed the largest displacement.

All these findings have raised the question of whether regional ventilation is different between spontaneous breathing and mechanical ventilation and whether mechanical ventilation worsens $\dot{V}_A/\dot{Q}$ as a consequence of poor ventilation of well-perfused, dependent lung regions. However, there is not much support for worsening of gas exchange by muscle paralysis if the lungs are normal (in contrast to injured lungs); there is also little support from the few studies of $\dot{V}_A/\dot{Q}$ distribution that have been performed. Dueck and colleagues[134] found the same increase in $\dot{V}_A/\dot{Q}$ mismatch in anesthetized sheep during anesthesia, regardless of whether they were spontaneously breathing or ventilated mechanically. The log SDQ, indicating the degree of mismatch, increased (0.66 [awake], 0.83 [inhaled anesthesia with spontaneous breathing], 0.89 [mechanical ventilation]). Shunt is also increased during anesthesia from 1% (awake) to 11% (anesthetized, spontaneous breathing) or 14% (anesthetized, mechanical ventilation). In a study of anesthetized human subjects, shunt and log SDQ increased from 1% and 0.47 while awake to 6% and 1.03 during anesthesia with spontaneous breathing and 8% and 1.01 during mechanical ventilation.[83] Thus most of the gas exchange effects of anesthesia occurs during spontaneous breathing, with little or no further derangement added by muscle paralysis and mechanical ventilation.

INCREASED OXYGEN FRACTION

In the studies cited thus far, an inspired oxygen fraction (FiO_2) of approximately 0.4 was used. Anjou-Lindskog and colleagues[135] induced anesthesia in subjects breathing air (FiO_2, 0.21) in middle-aged to older patients during intravenous anesthesia before elective lung surgery and found only small shunts of 1% to 2%, although log SDQ increased from 0.77 to 1.13. When FiO_2 was increased to 0.5, the shunt increased (by 3% to 4%). In another study of older patients during halothane anesthesia,[83] an increase in FiO_2 from 0.53 to 0.85 caused an increase in shunt from 7% to 10% of cardiac output. Thus increasing FiO_2 increases shunt, possibly because of attenuation of HPV by increasing FiO_2[121] or further development of atelectasis and shunt in lung units with low $\dot{V}_A/\dot{Q}$ ratios.[125]

BODY POSITION

FRC is reduced dramatically by the combined effect of the supine position and anesthesia. The effects on the FRC of inducing anesthesia in the upright position were tested by Heneghan and associates,[136] and there was no difference in oxygenation in the semirecumbent versus supine position. Decreased cardiac output and inhomogeneity of blood flow can outweigh any effects of posture. Fractional perfusion of the most dependent lung regions—likely poorly or not ventilated—may actually have been increased in the semirecumbent position. In the lateral position, differences in lung mechanics, resting lung volumes, and atelectasis formation between the dependent and nondependent portions of the lung have been demonstrated[137] and shown to result in further disturbance of the ventilation-perfusion match, with severe impairment in oxygenation. However, there are large and unpredictable inter-individual variations.[138] Using isotope techniques, an increase in $\dot{V}_A/\dot{Q}$ mismatch was also demonstrated in anesthetized, paralyzed patients in the lateral position,[139] and an improvement was noticed in the prone position.[140] In addition, the vertical inhomogeneity of perfusion distribution is less marked in the prone position,[68] possibly reflecting regional differences in vascular configuration that promote perfusion of dorsal lung regions, regardless of whether they are in a dependent or nondependent position. Finally, distribution of ventilation may be uniform in anesthetized subjects when prone.[141]

AGE

Oxygenation is less efficient in older patients.[10] However, the formation of atelectasis does not increase with age in adults, and the few CT studies of infants during anesthesia suggest greater degrees of atelectasis.[96] In addition, shunt is independent of age between 23 and 69 years. However, $\dot{V}_A/\dot{Q}$ mismatch increases with age, with enhanced perfusion of low $\dot{V}_A/\dot{Q}$ regions when awake and when anesthetized. The major cause of impaired gas exchange during anesthesia in those younger than 50 years is shunt, whereas beyond 50 years, $\dot{V}_A/\dot{Q}$ mismatch (i.e., increased log SDQ) becomes increasingly important (see Fig. 13.24). Because the correlation between log SDQ and age during anesthesia is almost parallel with that during the awake state, it can be said that anesthesia worsens $\dot{V}_A/\dot{Q}$ matching to the same extent as 20 years of aging.

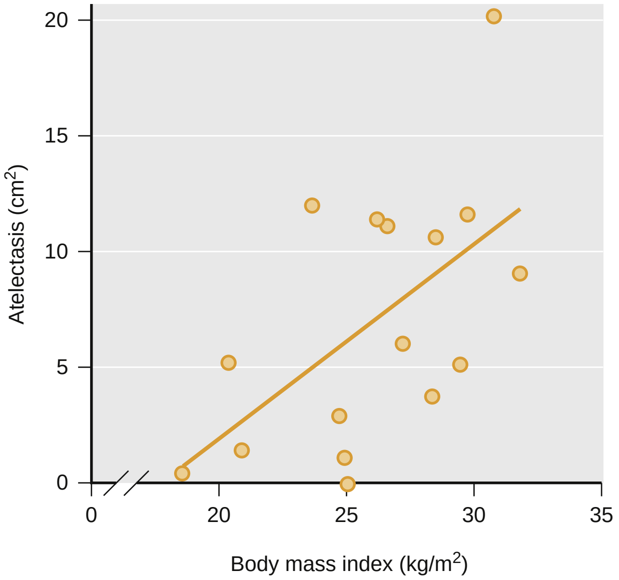

Fig. 13.25 Relationship between body mass index (BMI) and extent of atelectasis during general anesthesia. As BMI increases, so does the extent of atelectasis (although there is considerable variability). (From Rothen HU, Sporre B, Engberg G, Wegenius G, Hedenstierna G. Re-expansion of atelectasis during general anaesthesia: a computed tomography study. *Br J Anaesth.* 1993;71:788–795.)

OBESITY

Obesity worsens oxygenation[142,143] predominantly because of reduced FRC resulting in a greater propensity to airway closure.[144] In addition, the use of high inspired oxygen concentrations promotes rapid atelectasis formation in alveoli distal to closed airways,[87,109] and the atelectasis seems to be larger than in normal weight subjects (Fig. 13.25).[144,145]

Preventing a decrease in FRC by applying CPAP during induction of anesthesia probably reduces atelectasis formation, and thereby maintains oxygenation.[123,146,147] Indeed, the reduced “safety window” (the time taken to develop desaturation following breathing oxygen before induction of anesthesia) is much reduced in obese patients, and this may be prolonged by PEEP or CPAP[148] increasing lung volume and increasing the reservoir of O_2 available for diffusion into the capillary blood.

The use of high levels of inspired oxygen concentration, often almost 100%, to keep an acceptable level of oxygenation during anesthesia and surgery may be the simplest but not necessarily the best approach. It will promote further atelectasis formation,[108] and if the shunt is larger than 30%, which may be the case in these patients, additional oxygen will add little to arterial oxygenation.[149] The application of PEEP has been advocated, and it may reduce the atelectasis[122,144,146] but may also have adverse effects, such as propensity for aspiration, reduced cardiac output, and redistribution of blood flow toward residual collapsed lung regions. Ventilation with inflations close to VC to reopen collapsed tissue, followed by ventilation with added PEEP, is another option. Recruitment of the lung with inflation to 55 cm H_2O opened essentially all collapsed lung tissue in patients with a BMI of 40 kg/m² or more.[150] However, a recruitment alone did not keep the lung open for more than a few minutes. To keep the lung open, a PEEP of 10 cm H_2O after the recruitment was needed, and PEEP of 10 was not enough to open up the lung.[150] Body position can have a substantial effect on lung volume and should be considered to the extent that surgery allows.[151]

PREEXISTING LUNG DISEASE

Smokers and patients with chronic lung disease have impaired gas exchange in the awake state, and anesthesia-associated deterioration in oxygenation is greater than in healthy individuals.[10] Interestingly, smokers with moderate airflow limitation may have less shunt as measured by MIGET than in subjects with healthy lungs. Thus, in patients with mild to moderate bronchitis who were to undergo lung surgery or vascular reconstructive surgery in the leg, only a small shunt was noticed, but log SDQ was increased.[83] In patients with chronic bronchitis studied by MIGET and CT, no or limited atelectasis developed during anesthesia and no or only minor shunt;[101] however, a considerable mismatch was seen with a large perfusion fraction to low $\dot{V}_A/\dot{Q}$ regions. Consequently, arterial oxygenation was more impaired than in lung-healthy subjects, but the cause was different from that in healthy subjects. A possible reason for the absence of atelectasis and shunt in these patients is chronic hyperinflation, which changes the mechanical behavior of the lungs and their interaction with the chest wall such that the tendency to collapse is reduced. It should be kept in mind that a patient with obstructive lung disease may have large regions with low $\dot{V}_A/\dot{Q}$ ratios that can be converted over time to resorption atelectasis. Thus the protection against atelectasis formation during anesthesia by the obstructive lung disease might not last long. Regions with low $\dot{V}_A/\dot{Q}$ can be replaced by atelectasis as a result of slow absorption of gas behind occluded airways later during surgery and in the postoperative period.

REGIONAL ANESTHESIA

The ventilatory effects of regional anesthesia depend on the type and extension of motor blockade. With extensive blocks that include all the thoracic and lumbar segments, inspiratory capacity is reduced by 20% and expiratory reserve volume approaches zero.[152,153] Diaphragmatic function, however, is often spared, even in cases of inadvertent extension of subarachnoid or epidural sensory block up to the cervical segments.[152] Skillfully handled regional anesthesia affects pulmonary gas exchange only minimally. Arterial oxygenation and CO_2 elimination are well maintained during spinal and epidural anesthesia. This is in line with the findings of an unchanged relationship of CC and FRC,[154] and unaltered distributions of ventilation-perfusion ratios as assessed by MIGET during epidural anesthesia.[83]

CAUSES OF HYPOXEMIA AND HYPERCAPNIA

In the previous sections, we discussed ventilation, gas distribution, and the respiratory mechanics that govern distribution, diffusion, and pulmonary perfusion. All these components of lung function can affect the oxygenation of blood, and all except diffusion can also measurably affect CO_2 elimination. The different mechanisms behind hypoxemia and CO_2 retention, or hypercapnia or hypercarbia, have been mentioned previously but will be analyzed in more detail here.

TABLE 13.1 Causes of Hypoxemia

Disturbance	Pao_2 (Breathing Air) at Rest	Pao_2 (Breathing Oxygen) at Rest	Pao_2 (Breathing Air) With Exercise (Versus Rest)	$Paco_2$
Hypoventilation	Reduced	Normal	No change or further decrease	Increased
$\dot{V}_A/\dot{Q}$ mismatch	Reduced	Normal	No change or minor increase or decrease	Normal
Shunt	Reduced	Reduced	No change or further decrease	Normal
Diffusion impairment	Reduced	Normal	Small to large decrease	Normal

Pulmonary edema	–	+	+	++
Pulmonary emboli	–	–	++	+
Acute respiratory distress syndrome	–	–	+	+++

+++ Most Important; ++ Important; + Somewhat Important; – Unimportant.

Causes of hypoxemia include hypoventilation, $\dot{V}_A/\dot{Q}$ mismatch, impaired diffusion, and right-to-left shunt (Table 13.1). Hypercapnia is usually caused by hypoventilation, although it can be caused by $\dot{V}_A/\dot{Q}$ mismatch and shunt (Table 13.2). Increased $\dot{V}CO_2$ occurs in hypermetabolic conditions (e.g., fever, malignant hyperthermia, thyroid crisis) or with the use of CO_2-generating buffers such as sodium bicarbonate ($NaHCO_3$).

HYPOVENTILATION

If ventilation is low relative to metabolic demand, elimination of CO_2 will be inadequate, and CO_2 will accumulate in the alveoli, blood, and other body tissues. Hypoventilation is often defined as ventilation that results in a $Paco_2$ greater than 45 mm Hg (6 kPa). Thus hypoventilation could be present even when minute ventilation is high, provided the metabolic demand or dead space ventilation is increased to a greater extent.

The increased alveolar Pco_2 reduces the alveolar space available for oxygen. Alveolar PO_2 (PAO_2) can be estimated by the alveolar gas equation (see Box 13.1). The simplified equation is expressed:

$$PAO_2 = P_IO_2 - \left(\frac{PACO_2}{R}\right)$$

Assuming that the respiratory exchange ratio (R) is 0.8 (more or less true at rest), PAO_2 can be estimated. In the ideal lung, PaO_2 equals PAO_2. For example, if PiO_2 is 149 mm Hg (19.9 kPa) and $Paco_2$ is 40 mm Hg (5.3 kPa), then PaO_2 is 99 mm Hg (13.2 kPa). If hypoventilation develops and the $Paco_2$ rises to 60 mm Hg (8 kPa) and there is no other gas exchange impairment, the PaO_2 will fall to 74 mm Hg (9.9 kPa). Clearly, a decrease in PaO_2 caused by hypoventilation is easily overcome by increasing PiO_2 (i.e., by increasing FiO_2). If there is a gap between the PAO_2 (estimated from this equation) and the measured (actual) PaO_2, then a cause of hypoxemia in addition to hypoventilation is present. These causes are discussed in the following sections.

VENTILATION-PERFUSION MISMATCH

For optimal gas exchange, ventilation and perfusion must match each other in all lung regions. At rest, both ventilation and perfusion increase downward through the lung. However, perfusion increases more than ventilation, the difference between the uppermost and lowermost 5-cm segments being threefold for ventilation and tenfold for perfusion. This change results in a mean $\dot{V}_A/\dot{Q}$ ratio of approximately 1 somewhere in the middle of the lung and a range of $\dot{V}_A/\dot{Q}$ ratios (0.5 at the bottom, 5.0 in the apex; see Fig. 13.23, upper panel, the perfusion distribution being a simplified drawing of Fig. 13.11).

Another way of showing the matching between ventilation and blood flow is by illustrating a multicompartmental analysis of ventilation and distribution of blood flow against $\dot{V}_A/\dot{Q}$ ratios. This can be achieved with MIGET.[155] In short, MIGET is based on the constant intravenous infusion of a number of inert gases (usually six) with differing solubilities in blood. When passing through the lung capillaries, the different gases are eliminated via the alveoli and expired in indirect proportion to their solubility. A poorly

log SD$\dot{Q}$, Standard deviations of the logarithmic distribution of perfusion; log SD$\dot{V}$, standard deviations of the logarithmic distribution of ventilation; $\dot{Q}$ mean, mean $\dot{V}_A/\dot{Q}$ of the perfusion distribution; $\dot{V}$ mean, mean $\dot{V}_A/\dot{Q}$ of ventilation distribution. (Gunnarsson L, Tokics L, Gustavsson H, Hedenstierna G. Influence of age on atelectasis formation and gas exchange impairment during general anaesthesia. Br J Anaesth. 1991;66:423–432).

soluble gas will rapidly leave the bloodstream and be more or less completely eliminated and exhaled (e.g., sulfur hexafluoride); a gas with a high solubility in the blood will be almost completely retained in the blood and will not be exhaled (e.g., acetone); and a gas of intermediate solubility will be retained (and expired) to an intermediate extent (e.g., halothane).

As a result, the concentration of the different gases in arterial blood will differ, with higher concentrations of gases with high solubility. Retention can be calculated as the ratio between arterial and mixed venous blood concentrations. Similarly, the ratio of the concentrations (i.e., expired:mixed venous) can be calculated and gives the excretion for each gas. With knowledge of the retention, excretion, and solubility of each gas, an essentially continuous distribution of blood flow against $\dot{V}_A/\dot{Q}$ ratios can be constructed. The lower panel in Fig. 13.23 shows an example from a healthy subject. Note that ventilation and blood flow are well matched, being distributed to a limited number of compartments centered on a $\dot{V}_A/\dot{Q}$ ratio of 1. MIGET has a high discriminatory capacity of detecting different $\dot{V}_A/\dot{Q}$ disturbances, but does not provide topographic information. Several variables that reflect the degree of mismatch can be calculated and are shown in Table 13.3. In the following paragraphs, examples of $\dot{V}_A/\dot{Q}$ mismatch are discussed.

If ventilation and perfusion are not matched, gas exchange will be affected. The most common cause of impaired oxygenation is $\dot{V}_A/\dot{Q}$ mismatch. Low $\dot{V}_A/\dot{Q}$ will impede oxygenation because ventilation is insufficient to fully oxygenate the blood, and the degree of impairment is dependent on the degree of $\dot{V}_A/\dot{Q}$ mismatch; in fact, even normal lung regions $\dot{V}_A/\dot{Q}$ (0.5-1) cannot completely saturate the blood. Thus PaO_2 cannot equal alveolar PO_2, and a difference (PAO_2–PaO_2) of 3 to 5 mm Hg (0.4-0.7 kPa) is normal. With greater $\dot{V}_A/\dot{Q}$ mismatch, the PAO_2–PaO_2 difference is further increased. The $\dot{V}_A/\dot{Q}$ mismatch can account for all the hypoxemia seen in a patient with severe obstruction.[115] Shunt ($\dot{Q}$, but no $\dot{V}_A$), which is often claimed to exist in patients with COPD, is mostly absent when analyzed with a more sophisticated technique such as MIGET. Indeed, shunt in a patient with obstruction likely represents a complicating factor in the disease (Fig. 13.26).

In severe asthma, a distinct bimodal pattern of low ratios occurs when using MIGET (see Fig. 13.26).[156] The reason may be that alveoli behind airways obstructed by edema (or a mucous plug or spasm) can still be ventilated by collateral ventilation (i.e., alveolar pores, interbronchial communications); these regions would otherwise be shunt (no $\dot{V}_A$, some $\dot{Q}$), resulting in the additional peak in $\dot{V}_A/\dot{Q}$ explaining the bimodal distribution. Such collateral ventilation might be part of the reason that true shunt is not normally seen in COPD. Of course, if the standard shunt equation is used to explain hypoxemia, there is no capacity to distinguish between the contributions of low $\dot{V}_A/\dot{Q}$ versus shunt to hypoxemia (the net effect is best called *venous admixture*).

Airway obstruction is distributed unevenly, and a large variation in $\dot{V}_A/\dot{Q}$ ratios results. Indeed, ventilation is redistributed from regions with high airway resistance to other regions that can then become overventilated in proportion to their perfusion; this causes high $\dot{V}_A/\dot{Q}$ ratios. There are normally regions in the apex that have ratios of up to 5, but ratios of 100 or more exist in patients with obstruction, making the regions practically indistinguishable from true dead space; this is what causes the increase in physiologic dead space in obstructive lung disease. The effect of high $\dot{V}_A/\dot{Q}$ is also the same as for airway dead space—that is, ventilation that seems not to participate in gas exchange ("wasted ventilation"). Consequently, a patient with COPD has low $\dot{V}_A/\dot{Q}$ (impedes oxygenation) and high $\dot{V}_A/\dot{Q}$ (mimics dead space, impedes CO_2 elimination). However, MIGET is a complex, research-orientated tool, and the calculation of dead space for clinical purposes relies instead on expired CO_2. Derivation of the CO_2 dead space is shown in Box 13.3.

$\dot{V}_A/\dot{Q}$ mismatch exists to varying degrees in all patients with COPD, and it fully explains hypoxemia in most of them. Hypoventilation can also contribute, whereas impaired diffusion or shunt rarely contributes to hypoxemia. Diffusion capacity, or transfer test, can be reduced markedly in severe COPD, in particular in emphysema; in this case the decrease is not caused by thickened alveolar-capillary membranes but rather by reduced capillary blood volume and reduced area for diffusion.

Pulmonary vessels can be affected by lung disease and can cause $\dot{V}_A/\dot{Q}$ mismatch by impeding regional blood flow. Systemic diseases with vascular involvement can cause severe pulmonary dysfunction because of $\dot{V}_A/\dot{Q}$ mismatch, impaired diffusion, and shunt. $\dot{V}_A/\dot{Q}$ mismatch causes most of the hypoxemia in pulmonary fibrosis.[157] In addition, hypoxemia can be caused by impaired diffusion (in particular, during exercise, when it can dominate) and a varying degree of shunt (discussed later).

Pulmonary emboli cause $\dot{V}_A/\dot{Q}$ mismatch in three ways. First, vascular beds are occluded, causing extremely high $\dot{V}_A/\dot{Q}$ locally; this is manifest as increased dead space. Second, the occluded vascular bed diverts blood flow to other, already ventilated regions, thus converting these into low $\dot{V}_A/\dot{Q}$ regions. Finally, if P_{PA} (pulmonary artery pressure) is markedly increased, then any propensity to shunt will be increased.[158] In patients with acute pulmonary embolism,[159] hypoxemia appears to be principally caused by increased variability of $\dot{V}_A/\dot{Q}$, and this has been confirmed experimentally.[160]

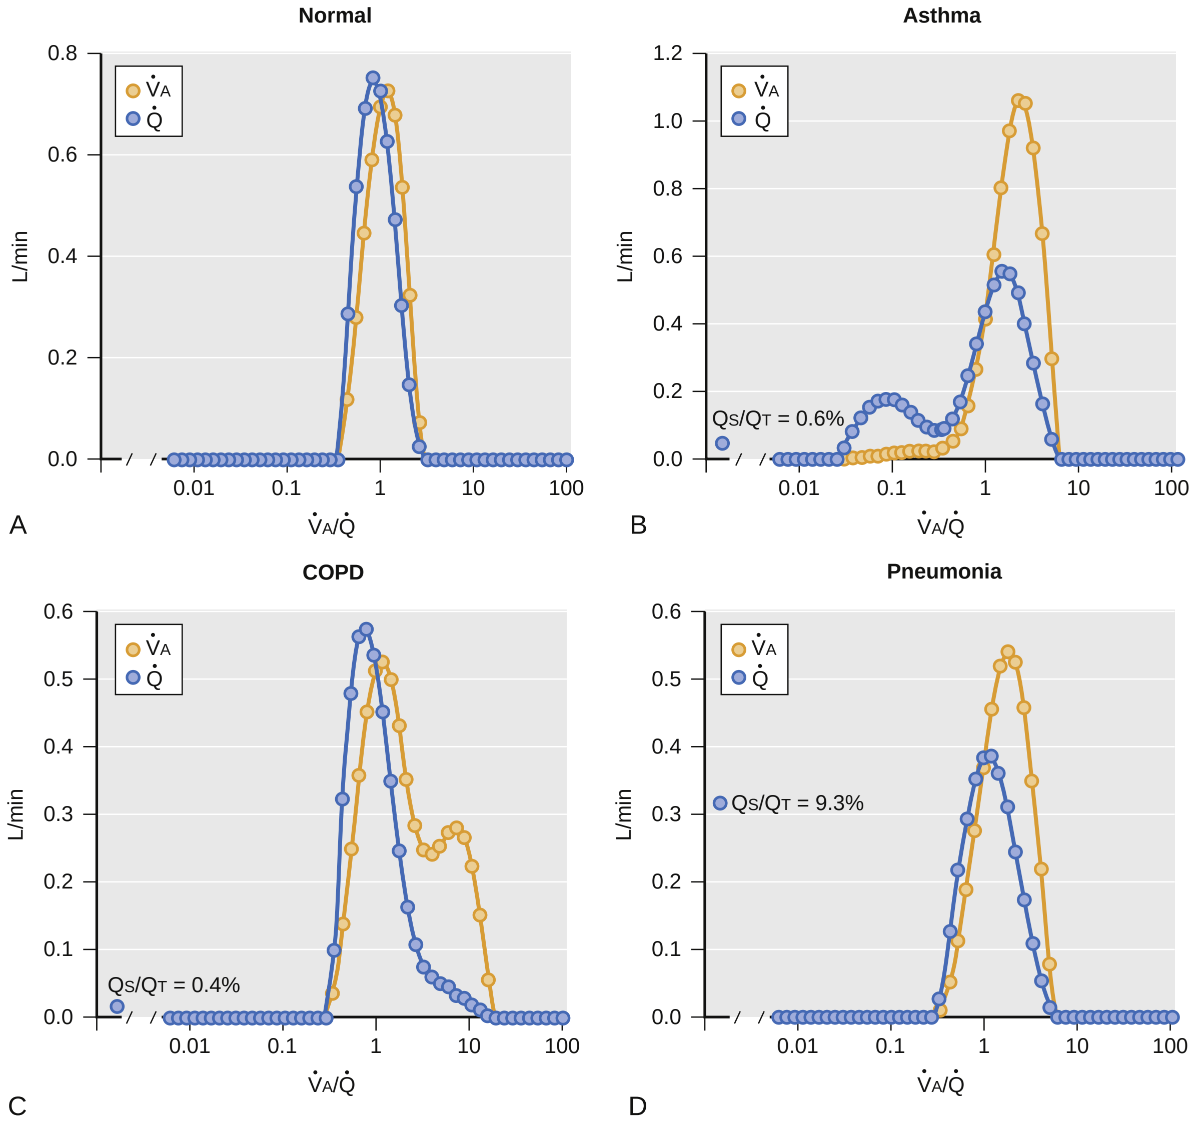

Fig. 13.26 Distribution of ventilation and perfusion in normal lungs, asthma, chronic obstructive pulmonary disease *(COPD)*, and pneumonia. In normal lungs (A) there is good matching between ventilation *(orange circle)* and perfusion *(blue circle)* with a mode centered around a $\dot{V}_A/\dot{Q}$ ratio of 1. This results in near optimal oxygenation of blood and CO_2 removal. In asthma (B) there is broader distribution of $\dot{V}_A/\dot{Q}$ with some regions being ventilated well in excess of perfusion ($\dot{V}_A/\dot{Q} = 10$ and greater), with another mode of low $\dot{V}_A/\dot{Q}$ centered around a ratio of 0.1. This mode can be explained by collateral ventilation maintaining gas exchange in alveoli behind occluded airways. There is no shunt seen in asthma. In COPD (C) the pattern is similar to asthma, but with an additional "high" $\dot{V}_A/\dot{Q}$ mode that adds to dead space such as ventilation. Shunt is not present, and the pattern of $\dot{V}_A/\dot{Q}$ distribution is not associated with significant hypoxemia. In lobar pneumonia (D) the major finding is pure shunt (consolidated, perfused, and poorly ventilated lobe); there is only minor widening of the $\dot{V}_A/\dot{Q}$ distribution.

Pneumonia involving large areas of consolidated, edematous, or atelectatic (i.e., all non-aerated) lung involves significant shunt, and areas of partial aeration contribute to $\dot{V}_A/\dot{Q}$ mismatch (see Fig. 13.26).[149] In bacterial pneumonia, HPV appears to be inhibited, which is an important mechanism that worsens hypoxemia.[161,162]

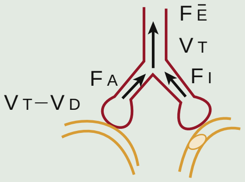
EFFECT OF $\dot{V}_A/\dot{Q}$ ON CO_2 ELIMINATION

A common misconception is that although $\dot{V}_A/\dot{Q}$ impedes oxygenation, it has little effect on CO_2 clearance. Actually, elimination of CO_2 is even more limited by $\dot{V}_A/\dot{Q}$ mismatch than is oxygenation of blood[82]; however, this seldom results in hypercapnia because minimal increases in $\dot{V}_A$ rapidly correct $Pa{CO_2}$. If alveolar ventilation is already impaired and cannot be increased, the addition of $\dot{V}_A/\dot{Q}$ mismatch will increase $Pa{CO_2}$.

IMPAIRED DIFFUSION

Hypoxemia can occur because of impaired diffusion in fibrosis or vascular diseases because of severely thickened alveolar-capillary membranes. Diffusion is slowed down and the entire length of capillary may be required before the capillary blood has been fully oxygenated, even in resting conditions. On the other hand, this means that a diffusion barrier is unlikely to cause hypoxemia provided the perfusion time and distance permits O_2 equilibration (see Fig. 13.12); however, when these reserves are spent, PaO_2 begins to fall. This decrease is particularly noticeable in patients with

BOX 13.3 Derivation of the Physiologic Dead Space Equation



The quantity of CO_2 expired in an exhaled tidal volume = $F_ECO_2 \times V_T$

This comes from perfused lung and from nonperfused lung.

CO_2 exhaled from perfused lung = $F_ACO_2 \times V_A = F_ACO_2 \times (V_T - V_D)$

CO_2 from nonperfused (dead space) lung is derived from inspired gas = $F_ICO_2 \times V_D$

Thus, $F_ECO_2 \times V_T = F_ACO_2(V_T \bullet V_D) + (F_ICO_2 \times V_D)$

By rearranging,

$$\frac{V_{DS}}{V_T} = \frac{F_A - F_E}{F_A - F_I}$$

If $F_I = 0$, F is replaced by P, and P_A is replaced by Pa, for CO_2,

$$\frac{V_{DS}}{V_T} = \frac{PaCO_2 - PECO_2}{PaCO_2}$$

where F_E, F_A, and F_I are mixed expired, alveolar, and inspired gas concentration, respectively, and V_T, V_{DS}, and V_A are tidal volume, dead space, and part of the tidal volume to perfused alveoli, respectively.

pulmonary fibrosis, who might have normal PaO_2 at rest but show dramatic decreases during exercise.[82,115] Development of -or increasing- right-to-left shunting in the heart, such as with an atrial septal defect, can also cause this exercise-induced hypoxemia because the left-to-right shunt at rest becomes right-to-left (or a small right-to-left shunt increases) because of increased P_{PA}.

RIGHT-TO-LEFT SHUNT

If blood passes through the lung without contacting ventilated alveoli, then the blood will not oxygenate or release CO_2. This condition is called a *shunt*, and it lowers PaO_2 and can increase $PaCO_2$. Healthy people have a small shunt (2%-3% of cardiac output) that is caused by venous drainage of the heart muscle into the left atrium by the thebesian veins. In pathologic states, the shunt ranges from 2% to 50% of cardiac output.

Shunt is often confused with $\dot{V}_A/\dot{Q}$ mismatch. While a $\dot{V}_A/\dot{Q}$ of zero (some perfusion, no ventilation) constitutes a shunt, there are two clear and important differences between low $\dot{V}_A/\dot{Q}$ and shunt. First, the anatomy of a shunt differs from an area of low $\dot{V}_A/\dot{Q}$. Regions with low $\dot{V}_A/\dot{Q}$ are characterized by narrowing of the airways and vasculature, which reduces ventilation and blood flow in some regions and increases them in others. Examples are obstructive lung disease and vascular disorders. Shunt is caused by the complete cessation of ventilation in a region, usually as a result of collapse (atelectasis) or consolidation (e.g., pneumonia). Asthma or COPD does not involve the formation of a shunt[115]; if a shunt is present, it indicates a complication. Second, supplemental O_2 improves the hypoxemia caused by low $\dot{V}_A/\dot{Q}$, but it has little effect on hypoxemia caused by shunt. Although aeration may be poor in regions of low $\dot{V}_A/\dot{Q}$, aeration does exist in these regions, and the concentration of O_2 in these alveoli can be enriched by increasing FiO_2. In contrast, supplemental O_2 cannot access the alveoli in a true (anatomic) shunt.

Anatomic shunt and low $\dot{V}_A/\dot{Q}$ usually coexist, and the net effect is sometimes referred to as *percent shunt* (per the standard shunt equation). In this situation, the low $\dot{V}_A/\dot{Q}$ component will contribute to the response from increasing FiO_2, and the regions of anatomic (true) shunt will not; therefore, shunt will always lower PaO_2 (at any FiO_2). When the calculated fraction increases to 25%, the response to increased FiO_2 will be small; when it increases to 30% or greater, the response will be negligible.[149] This varying response is the net effect of mixing blood with normal pulmonary end-capillary PO_2 and shunt blood, which has the same PO_2 as mixed venous blood. If shunt is a large enough fraction of total lung blood flow, the additional O_2 that can be physically dissolved by the raised FiO_2 is so small that it is almost immeasurable; such a shunt is said to be refractory.

RESPIRATORY FUNCTION DURING ONE-LUNG VENTILATION

Oxygenation can be a challenge during one-lung surgery. One lung is not ventilated but is still perfused, and in the postoperative period, restoration of lung integrity and ventilation–perfusion matching can take time.[163]

The technique of one-lung anesthesia and ventilation means that only one lung is ventilated and that the lung provides oxygenation of—and elimination of CO_2 from—the blood. Persisting perfusion through the nonventilated lung causes a shunt and decreases PaO_2 (Fig. 13.27); measures can be taken to reduce this blood flow.[164,165]

During one-lung anesthesia, there are two main contributors to impaired oxygenation: (1) the persisting blood flow through nonventilated lung and (2) development of atelectasis in the dependent lung, resulting in local shunt and low $\dot{V}_A/\dot{Q}$.[138] A recruitment maneuver can identify the influence of the dependent atelectasis;[166] serial increases in peak airway pressure and PEEP directed to the dependent, ventilated lung increased significantly the PaO_2, indicating that dependent atelectasis was an important cause of hypoxemia. In this situation, diversion of perfusion from the dependent (ventilated) to the nondependent (i.e., nonventilated) lung would have worsened oxygenation.

Recruitment can also affect V_D. Recruitment during one-lung anesthesia improved oxygenation, but also decreased V_D.[167] The slope of the CO_2 curve during a tidal expiration (phase III) was flatter, indicating a more even distribution of inspired gas throughout the lung and more synchronous alveolar emptying. Thus a secondary effect of recruiting collapsed lung tissue can be (presumably not when recruitment causes overinflation) more even distribution of ventilation and a decrease in the dead space fraction. This effect should facilitate the use of a smaller V_T. In contrast to an individual recruitment, the application of continuous elevated P_{AW} (PEEP titrated to optimal compliance in the ventilated lung) increased compliance by 10% but slightly worsened oxygenation, probably because of redistribution

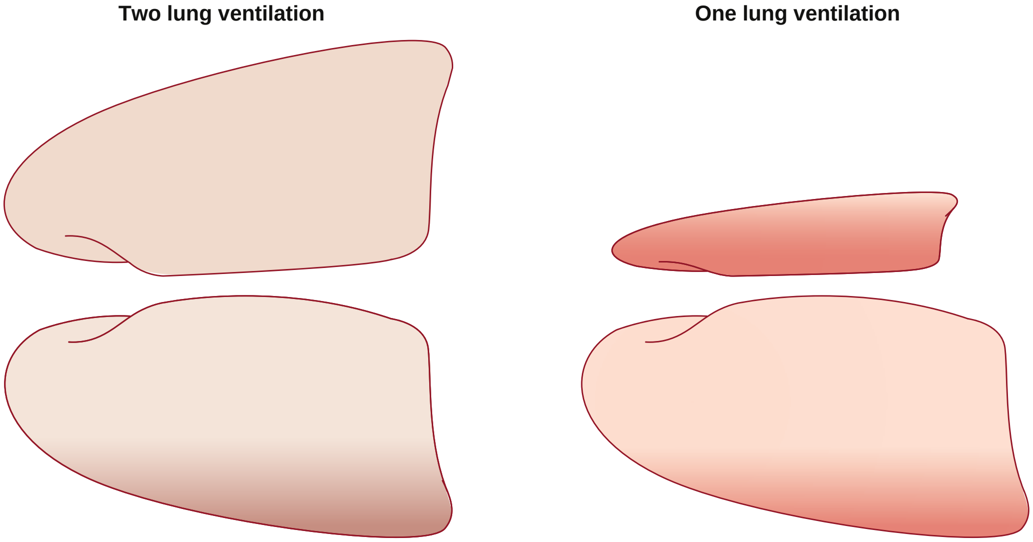


Fig. 13.27 Schematic drawing of the distribution of shunt during two-lung ventilation and one-lung ventilation during anesthesia. Shunt region is indicated by dark area in the lower lung during two-lung ventilation and in the lower lung—plus the entire upper lung—during one-lung ventilation.

of blood from the ventilated to the nonventilated (nondependent) lung.[168] The rationale for identifying and using optimal PEEP has also been reviewed.[169]

Maneuvers can also be applied to the nondependent lung. The effects of compressing the nondependent lung on oxygenation were examined using an intraarterial O_2 sensor, which provides instantaneous and continuous PaO_2.[170] Compression resulted in increased PaO_2, suggesting a shift of blood flow from the nondependent (nonventilated) to the dependent (ventilated) lung; development of complete absorption atelectasis in the nondependent lung may have similar effects.[171]

Inhaled NO (pulmonary vasodilator) and intravenous almitrine (pulmonary vasoconstrictor) have been studied alone and in combination. NO alone has little effect,[172] but oxygenation is improved when NO is combined with almitrine.[173,174] Almitrine alone also improves oxygenation[175] at a dose that does not alter P_{PA} or cardiac output. Although inhaled NO increases perfusion to already ventilated regions (increasing $\dot{V}_A/\dot{Q}$), almitrine potentiates HPV, decreasing perfusion to nonventilated (i.e., shunt) areas (reducing shunt) and potentially diverting blood flow to ventilated regions of the lung. Selective pulmonary vasodilation is reviewed.[176,177]

Careful analysis of the mechanical obstruction caused by kinking of pulmonary vessels and by HPV has shown that HPV is the important determinant of diversion of blood flow away from nonventilated lung (though not complete).[178] Moreover, positioning of the patient can affect the degree of shunting.[179]

PNEUMOPERITONEUM

Laparoscopic operations are usually performed by insufflation of CO_2 into the abdominal cavity. The effects are twofold. First, the consequences of hypercapnic acidosis[180,181] include depressed cardiac contractility, sensitization of the myocardium to the arrhythmogenic effects of catecholamines pulmonary vasoconstriction and systemic vasodilation.[182] There can also be long-lasting postoperative effects on breathing control.[183] In addition, the physical effects of pneumoperitoneum are important. These include decreased FRC and VC,[184] formation of atelectasis,[185] reduced respiratory compliance,[186] and increased peak airway pressure.[187] Nonetheless, shunt is reduced and arterial oxygenation is mostly improved during CO_2 pneumoperitoneum.[188] This paradox—more atelectasis and less shunt—suggests that efficient redistribution of blood flow away from collapsed lung regions is attributable to hypercapnic acidosis CO_2 potentiating hypoxic pulmonary vasoconstriction. Indeed, a recent experimental study showed that if the abdomen was inflated with air, a much larger shunt developed than if CO_2 had been used for inflation.[189]

Lung Function After Cardiac Surgery

Cardiac surgery produces the greatest degree of atelectasis in the postoperative period,[190] perhaps because both lungs are often collapsed. Spontaneous resolution of the atelectasis is gradual, leaving a residual shunt of up to 30% by day 1 or 2;[97,191] however, recruitment at the end of the case is possible. In some cases, 30 cm H_2O for 20 seconds is sufficient,[97] facilitated by the chest being open. A recruitment maneuver (with zero PEEP) causes transient increase in PaO_2 and end-expiratory lung volume (EELV), and with PEEP alone, EELV was increased but PaO_2 unchanged. However, a recruitment maneuver followed by PEEP resulted in a large and sustained increase in both PaO_2 and EELV.[192] The separation of effect whereby PEEP alone increases EELV to a greater extent than it increases oxygenation suggests further opening of an already opened lung rather than opening of atelectatic lung.

Head-to-head comparison of intermittent CPAP versus constant noninvasive pressure support ventilation reported intriguing findings. There was less radiographic evidence of atelectasis following pressure support, without differences in oxygenation of bedside pulmonary function testing.[193] Although the authors' conclusion was of no clinical benefit with noninvasive pressure support ventilation, differences in FiO_2 could cause differences in propensity to atelectasis. Recruitment maneuvers up to moderately high levels of airway pressure (46 cm H_2O) do not appear to affect the pulmonary vascular resistance or right ventricular afterload,[194] which is an issue of considerable importance following cardiac surgery. Nonetheless, it is prudent to consider RV loading and ejection in such circumstances, especially in the setting of diminished RV reserve or tricuspid regurgitation. Finally, many cardiac surgeries are now being performed "off pump," and the postoperative pulmonary effect is reduced, with less postoperative intrapulmonary shunt and correspondingly shorter hospital stays.[195]

Protective Ventilation

During the last few years, a concept of "protective ventilation" has appeared, based on three tools of ventilator support: (1) low tidal volume (assumed to reduce stress and strain of the lung), (2) recruitment maneuver (assumed to reopen any collapsed alveoli), and (3) PEEP (assumed to keep a recruited lung open during ongoing anesthesia and surgery).[196] These three tools have been adopted from intensive care, and one may ask whether they are equally useful in the mechanically ventilated, essentially lung healthy, anesthetized patient. As for (1) low tidal volume, a small tidal volume is reasonable, and a volume of 6 to 8 mL/kg/body weight, as is generally suggested, is the same size of what a normal subject is breathing spontaneously when awake. As for (2) recruitment maneuver and (3) PEEP, opening up and keeping the lung open is also reasonable and even important. Both a recruitment maneuver and PEEP will achieve this.

"Protective ventilation" has been claimed to reduce postoperative lung complications, although results vary between studies,[196,197] and which tool may be the most important remains also to be shown. Moreover, the protective ventilation concept covers the period from induction to emergence from anesthesia, and whether any positive effects remain in the postoperative period is unknown.[198] The atelectasis that develops intraoperatively may last for some days after surgery[199] and may be a cause of postoperative pulmonary complications. Further refinement of ventilatory support strategy may therefore rather be focused on the emergence from anesthesia and the postoperative period.

Postoperative Physiotherapy

Physiotherapy, much debated after surgery,[200] is associated with more effective lung recruitment (seen on thoracic CT) when involving deliberate approaches, such as flow bottles following exercise.[201] In effect, large and early inspiration following surgery may be key to preventing postoperative lung complications. Whether the deep inspiration needs to be accomplished with a specific forced breathing device is uncertain.

Intraoperative Hyperoxia

It has been suggested that ventilation with hyperoxic gas, 80% O_2, during anesthesia and for a couple of hours postoperatively will improve wound healing and reduce postoperative complications.[202] Based on a larger number of studies, the World Health Organization (WHO) presented guidelines in favor of perioperative hyperoxia.[203] However, the guidelines have met with criticism,[204] and large studies that have appeared after the publication of the guidelines do not support the use of hyperoxic gas.[205,206] Thus the potential advantage of elevating arterial oxygen tension may be offset by cellular responses with the formation of reactive oxygen species.[207]

Effect of Sleep on Respiration

Sleep has a major effect on many aspects of respiration, perhaps the most obvious being ventilation.[208] Sleep reduces V_T and inspiratory drive, and $\dot{V}_E$ falls by approximately 10%, depending on the sleep stage, with the most marked fall occurring during rapid-eye-movement (REM) sleep. Lung volume (i.e., FRC) is also reduced;[209] this commences almost immediately after the onset of sleep, and the lowest levels of FRC (down to 10% of resting levels) occur in REM sleep.[210] CT studies in healthy volunteers demonstrate that the sleep-induced decrease in FRC is accompanied by reduced aeration in the dependent lung.[211] Such loss in aeration was demonstrated in anesthetized patients when their FiO_2 was increased from 0.3 to 1.0; atelectasis developed rapidly. It is possible that during normal sleep, breathing with high levels of O_2 would also cause atelectasis.

Cardiac Physiology

LENA S. SUN and NICHOLAS A. DAVIS

KEY POINTS

- The cardiac cycle is the sequence of electrical and mechanical events during a single heartbeat.
- Cardiac output is determined by the heart rate, myocardial contractility, and preload and afterload.
- The majority of cardiomyocytes consist of myofibrils, which are rod-like bundles that form the contractile elements within the cardiomyocyte.
- The basic working unit of contraction is the sarcomere.
- Gap junctions are responsible for the electrical coupling of small molecules between cells.
- Action potentials have four phases in the heart.
- The key player in cardiac excitation-contraction coupling is the ubiquitous second messenger calcium.
- Calcium-induced sparks are spatially and temporally patterned activations of localized calcium release that are important for excitation-contraction coupling and regulation of automaticity and contractility.
- β-Adrenoreceptors stimulate chronotropy, inotropy, lusitropy, and dromotropy.
- Hormones with cardiac action can be synthesized and secreted by cardiomyocytes or produced by other tissues and delivered to the heart.
- Cardiac reflexes are fast-acting reflex loops between the heart and central nervous system that contribute to the regulation of cardiac function and the maintenance of physiologic homeostasis.

"To err, to be deceived, is human." This was William Harvey's gentle repudiation to fellow physicians in his 1628 "Exercitatio Anatomica de Motu Cordis et Sanguinis in Animalibus," in which he advanced the concepts of circulation with the heart as the central pump, a major break from the centuries-old anatomic teaching of Galen.[1,2] Modern cardiac physiology includes this as well as concepts of cellular and molecular biology of the cardiomyocyte and regulation of cardiac function by neural and humoral factors. This chapter focuses on the physiology of the heart, beginning with the intact heart and advancing to cellular cardiac physiology. Finally, the various factors that regulate cardiac function are briefly discussed.

The basic anatomy of the heart consists of two atria and two ventricles that provide two separate circulations in series. The pulmonary circulation, a low-resistance and high-capacitance vascular bed, receives output from the right side of the heart, and its chief function is bidirectional gas exchange. The left side of the heart provides output for the systemic circulation. It functions to deliver oxygen (O_2) and nutrients and to remove carbon dioxide (CO_2) and metabolites from various tissue beds.

Physiology of the Intact Heart

Understanding the mechanical performance of the intact heart begins with the knowledge of the phases of the cardiac cycle and the determinants of ventricular function.

CARDIAC CYCLE

The cardiac cycle is the sequence of electrical and mechanical events during a single heartbeat. Fig. 14.1 illustrates the electrical events of a single cardiac cycle represented by the electrocardiogram (ECG) with corresponding mechanical events. Left atrial and left ventricular pressures are shown correlated in time with aortic flow and ventricular volume.[3]

Intrinsic to the specialized cardiac pacemaker tissues is automaticity and rhythmicity. The cardiac cycle begins at the sinoatrial (SA) node with the initiation of the heartbeat. Because the SA node can generate impulses at the greatest frequency, it is the natural pacemaker.

Electrical Events and the Electrocardiogram

Electrical events of the pacemaker and the specialized conduction system are represented by the ECG at the body surface. The ECG is the result of differences in electrical potential generated by the heart at sites of the surface recording. The action potential initiated at the SA node is propagated to both atria by specialized conduction tissue that leads to atrial systole (contraction) and the P wave of the ECG. At the junction of the interatrial and interventricular septa, specialized atrial conduction tissue converges at the atrioventricular (AV) node, which is distally connected to the His bundle. The AV node is an area of relatively slow conduction, and a delay between atrial and ventricular contraction normally occurs at this locus. The PR interval represents the delay between atrial and ventricular contraction at the level of the AV node. From the distal His

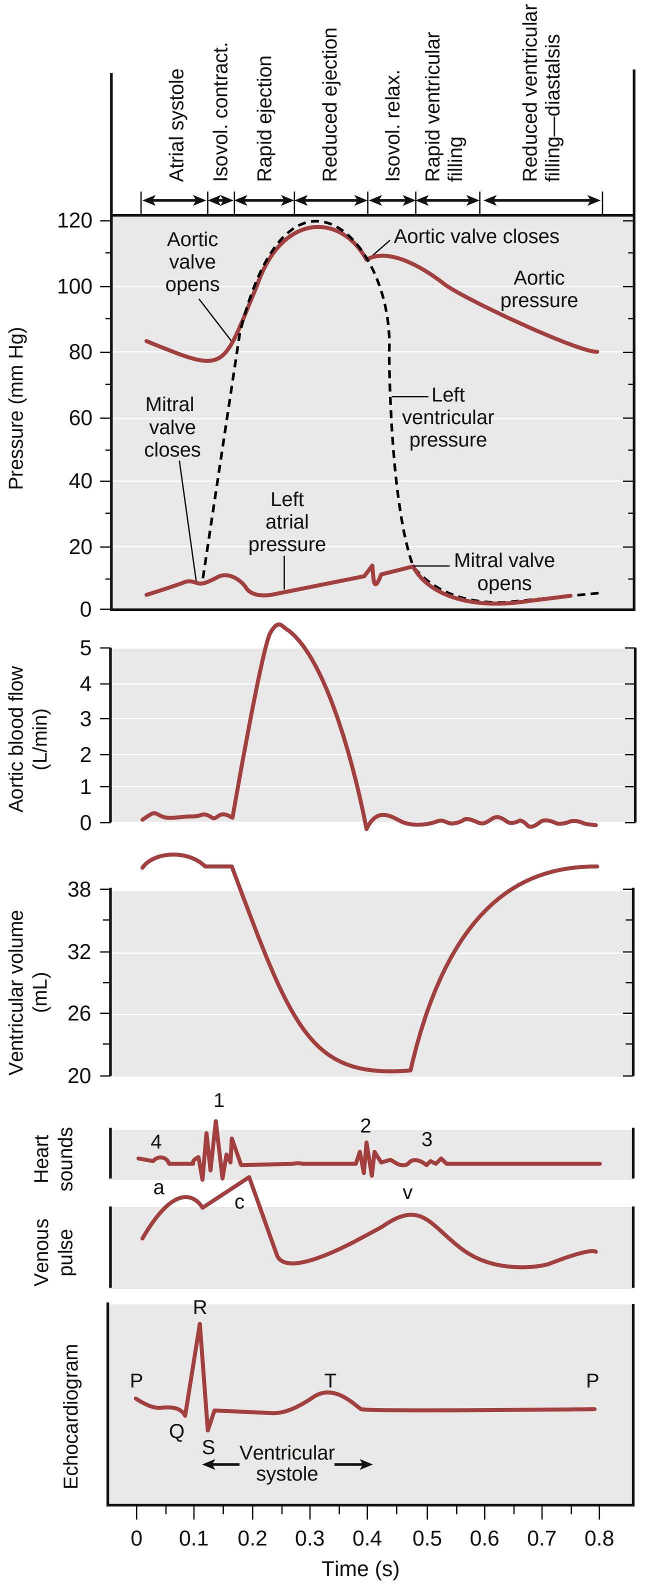

Fig. 14.1 Electrical and mechanical events during a single cardiac cycle. Aortic and atrial blood flow, ventricular volume, venous pulse, and the electrocardiogram are shown. (Berne RM, Levy MN: The cardiac pump. In *Cardiovascular physiology*, ed 8, St Louis, 2001, Mosby, pp 55-82.)

bundle, an electrical impulse is propagated through large left and right bundle branches and finally to the Purkinje system fibers, which are the smallest branches of the specialized conduction system. Finally, electrical signals are transmitted from the Purkinje system to individual ventricular cardiomyocytes. The spread of depolarization to the ventricular myocardium is exhibited as the QRS complex on the ECG. Depolarization is followed by ventricular repolarization and the appearance of the T wave on the ECG.[4]

Mechanical Events

The mechanical events of a cardiac cycle begin with the return of blood to the right and left atria from the systemic and pulmonary circulation, respectively. As blood accumulates in the atria, atrial pressure increases until it exceeds the pressure within the ventricle, and the AV valve opens. Blood passively flows first into the ventricular chambers, and such flow accounts for approximately 75% of the total ventricular filling.[5] The remainder of the blood flow is mediated by active atrial contraction or systole, known as the atrial "kick." The onset of atrial systole coincides with the depolarization of the SA node and the P wave. While the ventricles fill, the AV valves are displaced upward and ventricular contraction (systole) begins with closure of the tricuspid and mitral valves, which corresponds to the end of the R wave on the ECG. The first part of ventricular systole is known as isovolumic (or isometric) contraction. The electrical impulse traverses the AV region and passes through the right and left bundle branches into the Purkinje fibers, which leads to contraction of the ventricular myocardium and a progressive increase in intraventricular pressure. When intraventricular pressure exceeds pulmonary artery and aortic pressure, the pulmonic and aortic valves open and ventricular ejection occurs, which is the second part of ventricular systole.

Ventricular ejection is divided into the rapid ejection phase and the reduced ejection phase. During the rapid ejection phase, forward flow is maximal, and pulmonary artery and aortic pressure is maximally developed. In the reduced ejection phase, flow and great artery pressures taper with progression of systole. Pressures in both ventricular chambers decrease as blood is ejected from the heart, and ventricular diastole begins with closure of the pulmonic and aortic valves. The initial period of ventricular diastole consists of the isovolumic relaxation phase. This phase is concomitant with repolarization of the ventricular myocardium and corresponds to the end of the T wave on the ECG. The final portion of ventricular diastole involves a rapid decrease in intraventricular pressure until it decreases to less than that of the right and left atria, at which point the AV valve reopens, ventricular filling occurs, and the cycle repeats itself.

VENTRICULAR STRUCTURE AND FUNCTION

Ventricular Structure

The specific architectural order of the cardiac muscles provides the basis for the heart to function as a pump. The ellipsoid shape of the left ventricle (LV) is a result of the laminar layering of spiraling bundles of cardiac muscles (Fig. 14.2). The orientation of the muscle bundle is longitudinal in the subepicardial myocardium and circumferential

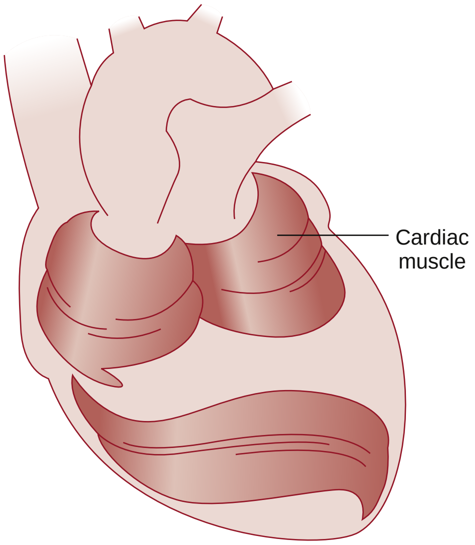

Fig. 14.2 Muscle bundles. (From Marieb EN. *Human Anatomy & Physiology*. 5th ed. San Francisco: Pearson Benjamin Cummings; 2001:684.)

in the middle segment and again becomes longitudinal in the subendocardial myocardium. Because of the ellipsoid shape of the LV, regional differences in wall thickness result in corresponding variations in the cross-sectional radius of the left ventricular chamber. These regional differences may serve to accommodate the variable loading conditions of the LV.[6] In addition, such anatomy allows the LV to eject blood in a corkscrew-type motion beginning from the base and ending at the apex. The architecturally complex structure of the LV thus allows maximal shortening of myocytes, which results in increased wall thickness and the generation of force during systole. Moreover, release of the twisted LV may provide a suction mechanism for filling of the LV during diastole. The left ventricular free wall and the septum have similar muscle bundle architecture. As a result, the septum moves inward during systole in a normal heart. Regional wall thickness is a commonly used index of myocardial performance that can be clinically assessed, such as by echocardiography or magnetic resonance imaging.

Unlike the LV, which needs to pump against the higher-pressure systemic circulation, the right ventricle (RV) pumps against a much lower pressure circuit in the pulmonary circulation. Consequently, wall thickness is considerably less in the RV. In contrast to the ellipsoidal form of the LV, the RV is crescent shaped; as a result, the mechanics of right ventricular contraction are more complex. Inflow and outflow contraction is not simultaneous, and much of the contractile force seems to be recruited from interventricular forces of the LV-based septum.

An intricate matrix of collagen fibers forms a scaffold of support for the heart and adjacent vessels. This matrix provides enough strength to resist tensile stretch. The collagen fibers are made up of mostly thick collagen type I fiber, which cross-links with the thin collagen type III fiber, the other major type of collagen.[7] Elastic fibers that contain elastin are in close proximity to the collagen fibers and account for the elasticity of the myocardium.[8]

Ventricular Function

The heart provides the driving force for delivering blood throughout the cardiovascular system to supply nutrients and to remove metabolic waste. Because of the anatomic complexity of the RV, the traditional description of systolic function is usually limited to the LV. Systolic performance of the heart is dependent on loading conditions and contractility. Preload and afterload are two interdependent factors extrinsic to the heart that govern cardiac performance.

Diastole is ventricular relaxation, and it occurs in four distinct phases: (1) isovolumic relaxation; (2) the rapid filling phase (i.e., the LV chamber filling at variable left ventricular pressure); (3) slow filling, or diastasis; and (4) final filling during atrial systole. The isovolumic relaxation phase is energy dependent. During auxotonic relaxation (phases 2 through 4), ventricular filling occurs against pressure. It encompasses a period during which the myocardium is unable to generate force, and filling of the ventricular chambers takes place. The isovolumic relaxation phase does not contribute to ventricular filling. The greatest amount of ventricular filling occurs in the second phase, whereas the third phase adds only approximately 5% of total diastolic volume and the final phase provides 15% of ventricular volume from atrial systole.

To assess diastolic function, several indices have been developed. The most widely used index for examining the isovolumic relaxation phase of diastole is to calculate the peak instantaneous rate of decline in left ventricular pressure ($-\mathrm{d}P/\mathrm{d}t$) or the time constant of isovolumic decline in left ventricular pressure (τ). The aortic closing-mitral opening interval and the isovolumic relaxation time and peak rate of left ventricular wall thinning, as determined by echocardiography, have both been used to estimate diastolic function during auxotonic relaxation. Ventricular compliance can be evaluated by pressure-volume relationships to determine function during the auxotonic phases of diastole.[9,10]

Many different factors influence diastolic function: magnitude of systolic volume, passive chamber stiffness, elastic recoil of the ventricle, diastolic interaction between the two ventricular chambers, atrial properties, and catecholamines. Whereas systolic dysfunction is a reduced ability of the heart to eject, diastolic dysfunction is a decreased ability of the heart to fill. Abnormal diastolic function is now recognized as the predominant cause of the pathophysiologic condition of congestive heart failure.[11]

Ventricular interactions during systole and diastole are internal mechanisms that provide feedback to modulate stroke volume (SV). Systolic ventricular interaction involves the effect of the interventricular septum on the function of both ventricles. Because the interventricular septum is anatomically linked to both ventricles, it is part of the load against which each ventricle has to work. Therefore, any changes in one ventricle will also be present in the other. In diastolic ventricular interaction, dilatation of either the LV or RV will have an impact on effective filling of the contralateral ventricle and thereby modify function.

Preload and Afterload. *Preload* is the ventricular load at the end of diastole, before contraction has started. First described by Starling, a linear relationship exists between

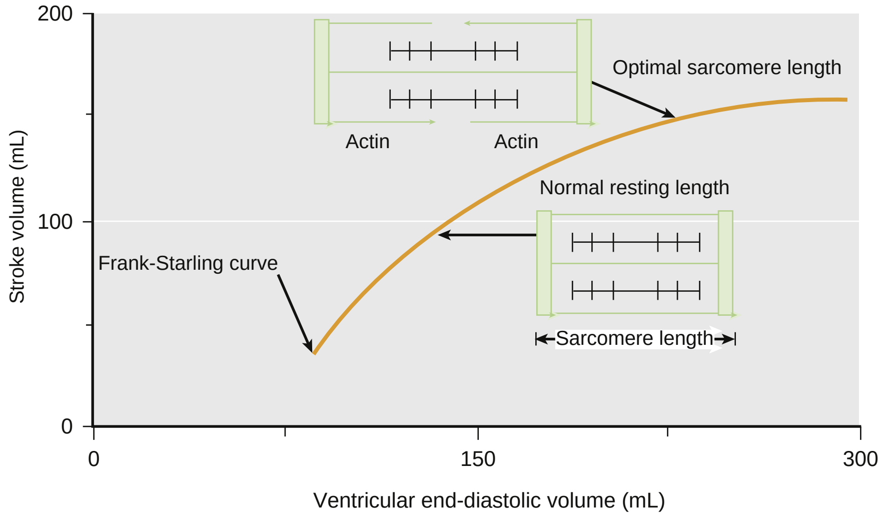

Fig. 14.3 Frank-Starling relationship. The relationship between sarcomere length and tension developed in cardiac muscles is shown. In the heart, an increase in end-diastolic volume is the equivalent of an increase in myocardial stretch; therefore, according to the Frank-Starling law, increased stroke volume is generated.

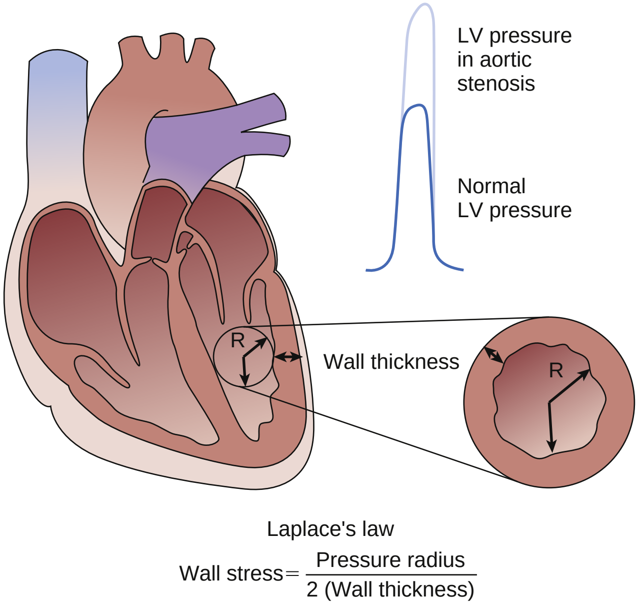
sarcomere length and myocardial force (Fig. 14.3). In clinical practice, surrogate representatives of left ventricular volume such as pulmonary wedge pressure or central venous pressure are used to estimate preload.[5] More direct measures of ventricular volumes can be made using echocardiography.

Afterload is the systolic load on the LV after contraction has begun. Aortic compliance is an additional determinant of afterload.[3] Aortic compliance is the ability of the aorta to give way to systolic forces from the ventricle. Changes in the aortic wall (dilation or stiffness) can alter aortic compliance and thus afterload. Examples of pathologic conditions that alter afterload are aortic stenosis and chronic hypertension. Both impede ventricular ejection, thereby increasing afterload. Aortic impedance, or aortic pressure divided by aortic flow at that instant, is an accurate means of gauging afterload. However, clinical measurement of aortic impedance is invasive. Echocardiography can noninvasively estimate aortic impedance by determining aortic blood flow at the time of its maximal increase. In clinical practice, the measurement of systolic blood pressure is adequate to approximate afterload, provided that aortic stenosis is not present.

Preload and afterload can be thought of as the wall stress that is present at the end of diastole and during left ventricular ejection, respectively. Wall stress is a useful concept because it includes preload, afterload, and the energy required to generate contraction. Wall stress and heart rate are probably the two most relevant indices that account for changes in myocardial O_2 demand. Laplace's law states that wall stress (σ) is the product of pressure (P) and radius (R) divided by wall thickness (h)[5]:

$$\sigma = P \times R/2h$$

The ellipsoid shape of the LV allows the least amount of wall stress such that as the ventricle changes its shape from ellipsoid to spherical, wall stress is increased. By using the ratio of the long axis to the short axis as a measure of the ellipsoid shape, a decrease in this ratio would signify a transition from ellipsoid to spherical.



$$\text{Wall stress} = \frac{\text{Pressure radius}}{2\ (\text{Wall thickness})}$$

Fig. 14.4 In response to aortic stenosis, left ventricular *(LV)* pressure increases. To maintain wall stress at control levels, compensatory LV hypertrophy develops. According to Laplace's law, wall stress = pressure · radius (*R*) ÷ (2 × wall thickness). Therefore, the increase in wall thickness offsets the increased pressure, and wall stress is maintained at control levels. (From Opie LH. Ventricular function. In: *Heart Physiology From Cell to Circulation*. 4th ed. Philadelphia: Lippincott-Raven; 2004:355–401.)

Thickness of the left ventricular muscle is an important modifier of wall stress. For example, in aortic stenosis, afterload is increased. The ventricle must generate a much higher pressure to overcome the increased load opposing systolic ejection of blood. To generate such high performance, the ventricle increases its wall thickness (left ventricular hypertrophy). By applying Laplace's law, increased left ventricular wall thickness will decrease wall stress, despite the necessary increase in left ventricular pressure to overcome the aortic stenosis (Fig. 14.4).[12] In a failing heart, the radius of the LV increases, thus increasing wall stress.

Frank-Starling Relationship. The Frank-Starling relationship is an intrinsic property of myocardium by which stretching of the myocardial sarcomere results in enhanced myocardial performance for subsequent contractions (see Fig. 14.3). In 1895, Otto Frank first noted that in skeletal muscle, the change in tension was directly related to its length, and as pressure changed in the heart, a corresponding change in volume occurred.[13] In 1914, E.H. Starling, using an isolated heart-lung preparation as a model, observed that "the mechanical energy set free on passage from the resting to the contracted state is a function of the length of the muscle fiber."[14] If a strip of cardiac muscle is mounted in a muscle chamber under isometric conditions and stimulated at a fixed frequency, then an increase in sarcomere length results in an increase in twitch force. Starling concluded that the increased twitch force was the result of a greater interaction of muscle bundles.

Electron microscopy has demonstrated that sarcomere length (2-2.2 μm) is positively related to the amount of actin and myosin cross-bridging and that there is an optimal sarcomere length at which the interaction is maximal. This concept is based on the assumption that the increase in cross-bridging is equivalent to an increase in muscle performance. Although this theory continues to hold true for skeletal muscle, the force-length relationship in cardiac muscle is more complex. When comparing force-strength relationships between skeletal and cardiac muscle, it is noteworthy that the reduction in force is only 10%, even if cardiac muscle is at 80% sarcomere length.[13] The cellular basis of the Frank-Starling mechanism is still being investigated and is briefly discussed later in this chapter. A common clinical application of Starling's law is the relationship of left ventricular end-diastolic volume and SV. The Frank-Starling mechanism may remain intact even in a failing heart.[15] However, ventricular remodeling after injury or in heart failure may modify the Frank-Starling relationship.

Contractility. Each Frank-Starling curve specifies a level of contractility, or the inotropic state of the heart, which is defined as the work performed by cardiac muscle at any given end-diastolic fiber. Factors that modify contractility will create a family of Frank-Starling curves with different contractility (Fig. 14.5).[12] Factors that modify contractility are exercise, adrenergic stimulation, changes in pH, temperature, and drugs such as digitalis. The ability of the LV to develop, generate, and sustain the necessary pressure for the ejection of blood is the intrinsic inotropic state of the heart.

In isolated muscle, the maximal velocity of contraction (V_{max}) is defined as the maximal velocity of ejection at zero load. V_{max} is obtained by plotting the velocity of muscle shortening in isolated papillary muscle at varying degrees of force. Although this relationship can be replicated in isolated myocytes, V_{max} cannot be measured in an intact heart because complete unloading is impossible. To measure the intrinsic contractile activity of an intact heart, several strategies have been attempted with varying success. Pressure-volume loops, albeit requiring catheterization of the left side of the heart, are currently the best way to determine contractility in an intact heart (Fig. 14.6).[12] The pressure-volume loop represents an indirect measure of the Frank-Starling relationship between force (pressure) and muscle length (volume). Clinically, the most commonly used noninvasive index of ventricular contractile function is the ejection fraction, which is assessed by echocardiography, angiography, or radionuclide ventriculography.

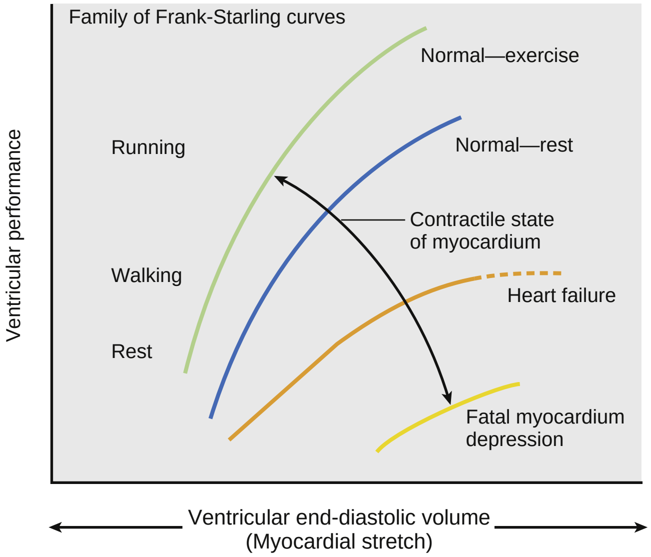


Fig. 14.5 A family of Frank-Starling curves is shown. A leftward shift of the curve denotes enhancement of the inotropic state, whereas a rightward shift denotes decreased inotropy. (From Opie LH. Ventricular function. In: *Heart Physiology From Cell to Circulation.* 4th ed. Philadelphia: Lippincott-Raven; 2004:355–401.)

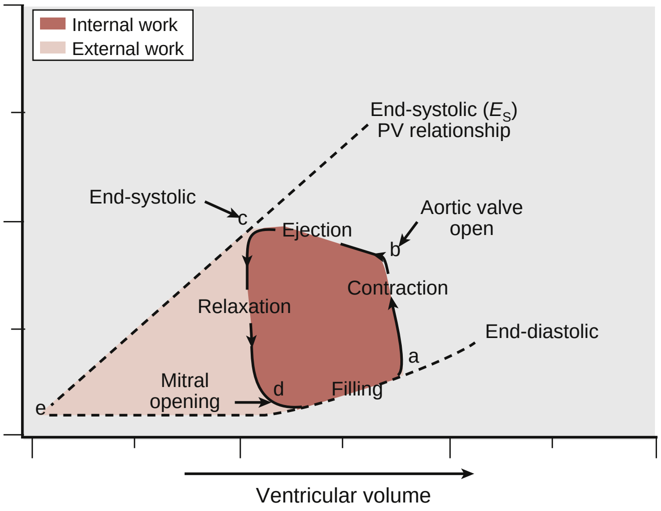

Fig. 14.6 Pressure-volume (PV) loop. Point *a* depicts the start of isovolumetric contraction. The aortic valve opens at point *b,* and ejection of blood follows *(points b→c).* The mitral valve opens at point *d,* and ventricular filling ensues. External work is defined by points *a, b, c,* and *d,* and internal work is defined by points *e, d,* and *c.* The PV area is the sum of external and internal work. (From Opie LH. Ventricular function. In: *Heart Physiology From Cell to Circulation.* 4th ed. Philadelphia: Lippincott-Raven; 2004:355–401.)

$$\text{Ejection fraction} = (\text{LVEDV} - \text{LVESV})/\text{LVEDV}$$

where LVESV is left ventricular end-systolic volume.

Cardiac Work. The work of the heart can be divided into external and internal work. External work is expended to eject blood under pressure, whereas internal work is expended within the ventricle to change the shape of the heart and to prepare it for ejection. Internal work contributes to inefficiency in the performance of the heart. Wall stress is directly proportional to the internal work of the heart.[16]

External work, or stroke work, is a product of the SV and pressure (P) developed during ejection of the SV.

$$\text{Stroke work} = \text{SV} \times P \text{ or } (\text{LVEDV} - \text{LVESV}) \times P$$

The external work and internal work of the ventricle both consume O_2. The clinical significance of internal work is illustrated in the case of a poorly drained LV during cardiopulmonary bypass. Although external work is provided by the roller pump during bypass, myocardial ischemia can still occur because poor drainage of the LV creates tension on the left ventricular wall and increases internal work.

The efficiency of cardiac contraction is estimated by the following formula[10]:

$$\text{Cardiac efficiency} = \text{External work}/\text{Energy equivalent of } O_2\text{consumption}$$

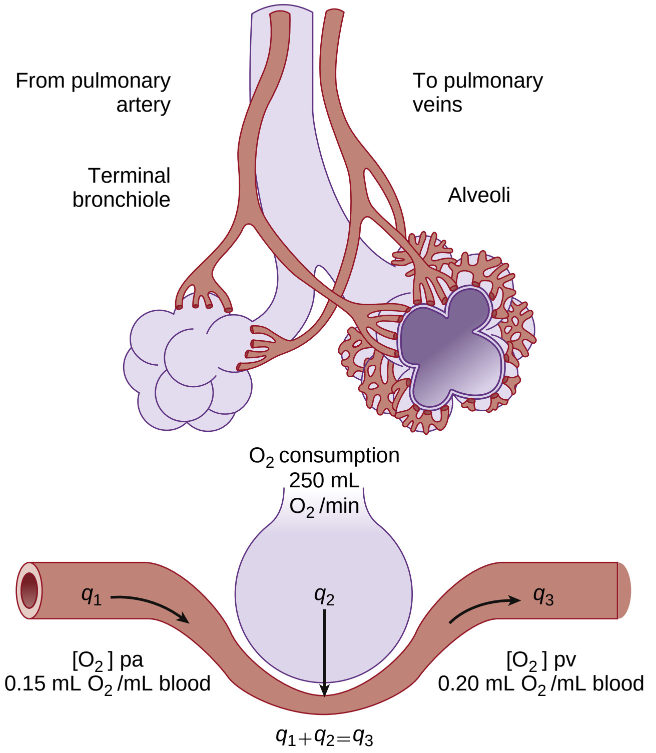
The corkscrew motion of the heart for the ejection of blood is the most favorable in terms of work efficiency, based on the architecture in a normal LV (with the cardiac muscle bundles arranged so that a circumferentially oriented middle layer is sandwiched by longitudinally oriented outer layers). In heart failure, ventricular dilation reduces cardiac efficiency because it increases wall stress, which in turn increases O_2 consumption.[13]

Heart Rate and Force-Frequency Relationship. In isolated cardiac muscle, an increase in the frequency of stimulation induces an increase in the force of contraction. This relationship is termed the *treppe*, which means *staircase* in German, and is the phenomenon of the force-frequency relationship.[10,17] At between 150 and 180 stimuli per minute, maximal contractile force is reached in an isolated heart muscle at a fixed muscle length. Thus, an increased frequency incrementally increases inotropy, whereas stimulation at a lower frequency decreases contractile force. However, when the stimulation becomes extremely rapid, the force of contraction decreases. In the clinical context, pacing-induced positive inotropic effects may be effective only up to a certain heart rate, based on the force-frequency relationship. In a failing heart, the force-frequency relationship may be less effective in producing a positive inotropic effect.[10]

CARDIAC OUTPUT

Cardiac output is the amount of blood pumped by the heart per unit of time ($\dot{Q}$) and is determined by four factors: two factors that are intrinsic to the heart—heart rate and myocardial contractility—and two factors that are extrinsic to the heart but functionally couple the heart and the vasculature—preload and afterload.

Heart rate is defined as the number of beats per minute and is mainly influenced by the autonomic nervous system. Increases in heart rate escalate cardiac output if ventricular filling is adequate during diastole. *Contractility* can be defined as the intrinsic level of contractile performance that is independent of loading conditions. Contractility is difficult to define in an intact heart because it cannot be separated from loading conditions.[10,17] For example, the *Frank-Starling relationship* is defined as the change in intrinsic contractile performance, based on changes in preload. Cardiac output in a living organism can be measured with the Fick principle (a schematic depiction is illustrated in Fig. 14.7).[3]



From pulmonary artery
To pulmonary veins
Terminal bronchiole
Alveoli
O_2 consumption 250 mL O_2/min
q_1
q_2
q_3
$[O_2]$ pa 0.15 mL O_2/mL blood
$[O_2]$ pv 0.20 mL O_2/mL blood
$q_1+q_2=q_3$

Fig. 14.7 Illustration demonstrates the principle of determination of cardiac output according to the Fick formula. If the oxygen (O_2) concentration in pulmonary arterial blood ($CpaO_2$), the O_2 concentration of the pulmonary vein ($CpvO_2$), and the O_2 consumption are known, then cardiac output can be calculated. *pa,* Pulmonary artery; *pv,* pulmonary vein. (Berne RM, Levy MN: The cardiac pump. In *Cardiovascular physiology*, ed 8, St Louis, 2001, Mosby, pp 55-82.)

The Fick principle is based on the concept of conservation of mass such that the O_2 delivered from pulmonary venous blood (q_3) is equal to the total O_2 delivered to pulmonary capillaries through the pulmonary artery (q_1) and the alveoli (q_2).

The amount of O_2 delivered to the pulmonary capillaries by way of the pulmonary arteries (q_1) equals total pulmonary arterial blood flow ($\dot{Q}$) times the O_2 concentration in pulmonary arterial blood ($CpaO_2$):

$$q_1 = \dot{Q} \times CpaO_2$$

The amount of O_2 carried away from pulmonary venous blood (q_3) is equal to total pulmonary venous blood flow ($\dot{Q}$) times the O_2 concentration in pulmonary venous blood ($CpvO_2$):

$$q_3 = \dot{Q} \times CpvO_2$$

The pulmonary arterial O_2 concentration is the mixed systemic venous O_2, and the pulmonary venous O_2

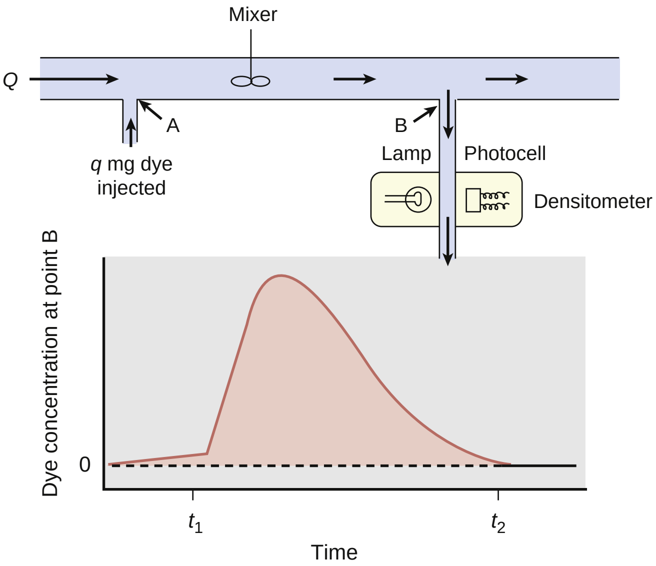


Fig. 14.8 Illustration demonstrates the principle of determining cardiac output with the indicator dilution technique. This model assumes that there is no recirculation. A known amount of dye *(q)* is injected at point *A* into a stream flowing at $\dot{Q}$ (mL/min). A mixed sample of the fluid flowing past point *B* is withdrawn at a constant rate through a densitometer. The change in dye concentration over time is depicted in a curve. Flow may be measured by dividing the amount of indicator injected upstream by the area under the downstream concentration curve. (Berne RM, Levy MN: The cardiac pump. In *Cardiovascular physiology*, ed 8, St Louis, 2001, Mosby, pp 55-82.)

concentration is the peripheral arterial O_2. O_2 consumption is the amount of O_2 delivered to the pulmonary capillaries from the alveoli (q_2). Because $q_1 + q_2 = q_3$,

$$\dot{Q}\,(CpaO_2) + q_2 = \dot{Q}\,(CpvO_2)$$

$$q_2 = \dot{Q}\,(CpvO_2) - \dot{Q}\,(CpaO_2)$$

$$q_2 = \dot{Q}\,(CpvO_2 - CpaO_2)$$

$$\dot{Q} = q_2/\,(CpvO_2 - CpaO_2)$$

Thus, if the $CpaO_2$, $CpvO_2$, and O_2 consumption (q_2) are known, then the cardiac output can be determined.

The indicator dilution technique is another method for determining cardiac output also based on the law of conservation of mass. The two most commonly used indicator dilution techniques are the dye dilution and the thermodilution methods. Fig. 14.8 illustrates the principles of the dye dilution method.[3]

Cellular Cardiac Physiology

CELLULAR ANATOMY

At the cellular level, the heart consists of three major components: cardiac muscle tissue (contracting cardiomyocytes), conduction tissue (conducting cells), and extracellular connective tissue. A group of cardiomyocytes with its connective tissue support network or extracellular matrix make up a myofiber (Fig. 14.9). Adjacent myofibers are connected by strands of collagen. The extracellular matrix is the synthetic product of fibroblasts and is made up of collagen, which is the main determinant of myocardial stiffness, and other major matrix proteins. One of the matrix proteins, elastin, is the chief constituent of elastic fibers. The elastic fibers account for, in part, the elastic properties of the myocardium.[8] Other matrix proteins include the glycoproteins or proteoglycans and matrix metalloproteinases. Proteoglycans are proteins with short sugar chains, and they include heparan sulfate, chondroitin, fibronectin, and laminin. Matrix metalloproteins are enzymes that degrade collagen and other extracellular proteins. The balance between the accumulation of extracellular matrix proteins by synthesis and their breakdown by matrix metalloproteins contributes to the mechanical properties and function of the heart.[8]

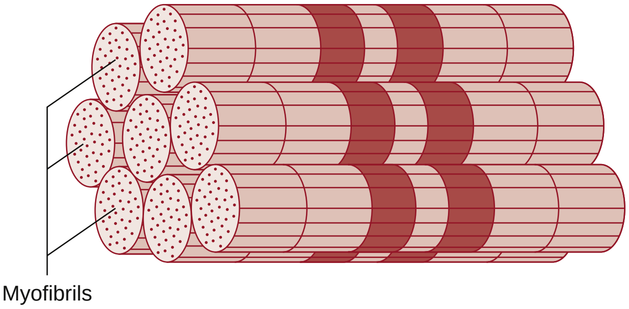

Fig. 14.9 Organization of cardiomyocytes. Fifty percent of cardiomyocyte volume is made up of myofibrils; the remainder consists of mitochondria, nucleus, sarcoplasmic reticulum, and cytosol.

CARDIOMYOCYTE STRUCTURE AND FUNCTION

Individual contracting cardiomyocytes are large cells between 20 μm (atrial cardiomyocytes) and 140 μm (ventricular cardiomyocytes) in length. Approximately 50% of the cell volume in a contracting cardiomyocyte is made up of myofibrils, and the remainder consists of mitochondria, nucleus, sarcoplasmic reticulum (SR), and cytosol. The myofibril is the rod-like bundle that forms the contractile elements within cardiomyocytes. Within each contractile element are contractile proteins, regulatory proteins, and structural proteins. Contractile proteins make up approximately 80% of the myofibrillar protein, with the remainder being regulatory and structural proteins.[18,19] The basic unit of contraction is the sarcomere (see discussion under Contractile Elements later in this chapter).

The sarcolemma, or the outer plasma membrane, separates the intracellular and extracellular space. It surrounds the cardiomyocyte and invaginates into the myofibrils through an extensive tubular network known as *transverse tubules* or *T tubules*, and it also forms specialized intercellular junctions between cells.[20,21]

Transverse or T tubules are in close proximity to an intramembranous system and the SR, which plays an important role in the calcium (Ca^{2+}) metabolism that is critical in the excitation-contraction coupling (ECC) of the cardiomyocyte. The SR can be further divided into the longitudinal (or network) SR and the junctional SR. The longitudinal SR is involved in the uptake of Ca^{2+} for the initiation of relaxation. The junctional SR contains large Ca^{2+}-release channels (ryanodine receptors [RyRs]) that release SR Ca^{2+} stores in response to depolarization-stimulated Ca^{2+} influx through the sarcolemmal Ca^{2+} channels. The RyRs are not only

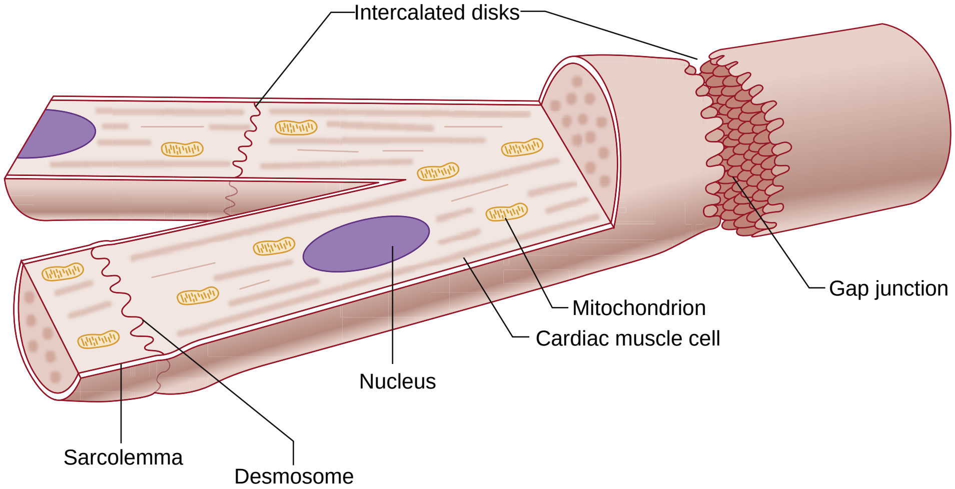

Fig. 14.10 The sarcolemma that envelops cardiomyocytes becomes highly specialized to form the intercalated disks where ends of neighboring cells are in contact. The intercalated disks consist of gap junctions and *spot* and *sheet* desmosomes.

Ca^{2+}-release channels, but they also form the scaffolding proteins that anchor many of the key regulatory proteins.[22]

Mitochondria are immediately found beneath the sarcolemma, wedged between myofibrils within the cell. They contain enzymes that promote the generation of adenosine triphosphate (ATP), and they are the energy powerhouse for the cardiomyocyte. In addition, mitochondria can also accumulate Ca^{2+} and thereby contribute to the regulation of the cytosolic Ca^{2+} concentration. Nearly all the genetic information is found within the centrally located nucleus. The cytosol is the fluid-filled microenvironment within the sarcolemma, exclusive of the organelles and the contractile apparatus and proteins.

Cardiac muscle cells contain three different types of intercellular junctions: gap junctions, *spot* desmosomes, and *sheet* desmosomes (or fasciae adherens) (Fig. 14.10).[20,23] Gap junctions are responsible for electrical coupling and the transfer of small molecules between cells, whereas desmosome-like junctions provide mechanical linkage. The adhesion sites formed by spot desmosomes anchor the intermediate filament cytoskeleton of the cell; those formed by the fasciae adherens anchor the contractile apparatus. Gap junctions consist of clusters of plasma membrane channels directly linking the cytoplasmic compartments of neighboring cells. Gap junction channels are constructed from connexins, a multigene family of conserved proteins. The principal connexin isoform of the mammalian heart is connexin 43; other connexins, notably connexins 40, 45, and 37, are also expressed but in smaller quantities.[22,23]

The conducting cardiomyocytes, or Purkinje cells, are cells specialized for conducting propagated action potentials. These cells have a low content of myofibrils and a prominent nucleus, and they contain an abundance of gap junctions. Cardiomyocytes can be functionally separated into (1) the excitation system, (2) the ECC system, and (3) the contractile system.

Excitation System

The cellular action potential originating in the specialized conduction tissue is propagated to individual cells where it initiates the intracellular event that leads to the contraction of the cell through the sarcolemmal excitation system.

Action Potential. Ion fluxes across plasma membranes result in depolarization (attaining a less negative membrane potential) and repolarization (attaining a more negative membrane potential). They are mediated by membrane proteins with ion-selective pores. Because these ion channel proteins open and close the pores in response to changes in membrane potential, the channels are voltage gated. In the heart, sodium (Na^+), potassium (K^+), Ca^{2+}, and chloride (Cl−) channels contribute to the action potential.

The types of action potential in the heart can be separated into two categories: (1) fast-response action potentials, which are found in the His-Purkinje system and atrial or ventricular cardiomyocytes; and (2) slow-response action potentials, which are found in the pacemaker cells in the SA and AV nodes. A typical tracing of an action potential in the His-Purkinje system is depicted in Fig. 14.11.[10] The electrochemical gradient for K^+ across the plasma membrane is the determinant for the resting membrane potential. Mostly as a result of the influx of Na^+, the membrane potential becomes depolarized, which leads to an extremely rapid upstroke (phase 0). As the membrane potential reaches a critical level (or threshold) during depolarization, the action potential is propagated. The rapid upstroke is followed by a transient repolarization (phase 1). Phase 1 is a period of brief and limited repolarization that is largely attributable to the activation of a transient outward K^+ current, i_{to}. The plateau phase (phase 2) occurs with a net influx of Ca^{2+} through L-type Ca^{2+} channels and the efflux of K^+ through several K^+ channels—the inwardly rectifying i_k, the delayed rectifier i_{k1}, and i_{to}. Repolarization (phase 3) is brought about when an efflux of K^+ from the three outward K^+ currents exceeds the influx of Ca^{2+}, thus returning the membrane to the resting potential. Very little ionic flux occurs during diastole (phase 4) in a fast-response action potential.

In contrast, during diastole (phase 4), pacemaker cells that show slow-response action potentials have the capability of spontaneous diastolic depolarization and generate the automatic cardiac rhythm. Pacemaker currents during phase 4 are the result of an increase in the three inward currents and a decrease in the two outward currents. The three

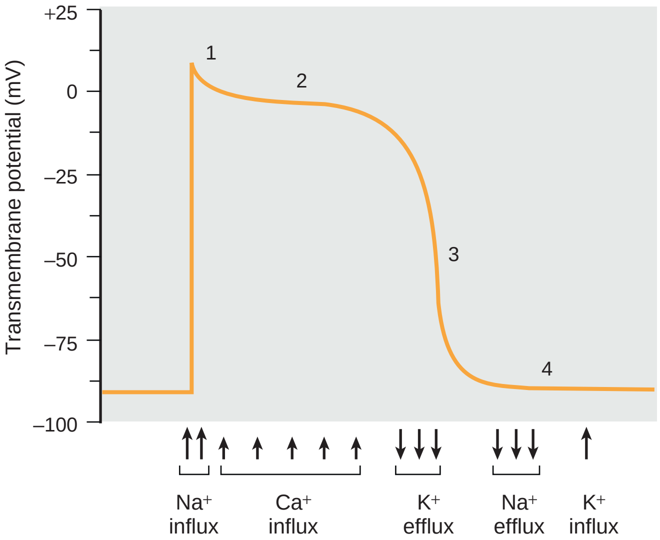

Fig. 14.11 Phases of cellular action potentials and major associated currents in ventricular myocytes. The initial phase (0) spike and overshoot (1) are caused by a rapid inward sodium (Na$^+$) current, the plateau phase (2) by a slow calcium (Ca^{2+}) current through L-type Ca channels, and repolarization (phase 3) by outward potassium (K$^+$) currents. Phase 4, the resting potential (Na$^+$ efflux, K$^+$ influx), is maintained by Na$^+$-K$^+$-adenosine triphosphatase (ATPase). The Na$^+$-Ca^{2+} exchanger is mainly responsible for extrusion of Ca^{2+}. In specialized conduction system tissue, spontaneous depolarization takes place during phase 4 until the voltage resulting in opening of the Na channel is reached. (From LeWinter MM, Osol G. Normal physiology of the cardiovascular system. In Fuster V, Alexander RW, O'Rourke RA, eds. *Hurst's the Heart.* 10th ed. New York: McGraw-Hill; 2001:63–94.)

inward currents that contribute to spontaneous pacemaker activity include two carried by Ca^{2+}, i_{CaL} and i_{CaT}, and one that is a mixed cation current, I_f.[24] The two outward currents are the delayed rectifier K$^+$ current, i_k, and the inward rectifying K$^+$ current, i_{k1}. When compared with the fast-response action potential, phase 0 is much less steep, phase 1 is absent, and phase 2 is indistinct from phase 3 in the slow-response action potential.[25] In SA node cells, the pacemaker I_f current is the principal determinant of duration diastolic depolarization, and it is encoded by four members of the hyperpolarization-activated cyclic nucleotide-gated gene (HCN1-4) family.[26]

During the cardiac action potential, movement of Ca^{2+} into the cell and Na$^+$ out of the cell creates an ionic imbalance. The Na$^+$-Ca^{2+} exchanger restores cellular ionic balance by actively transporting Ca^{2+} out of the cell against a concentration gradient while moving Na$^+$ into the cell in an energy-dependent manner.

Excitation-Contraction Coupling

Structures that participate in cardiac ECC include the sarcolemma, transverse tubules, SR, and myofilaments (Fig. 14.12A).[27] The process of ECC begins with depolarization of the plasma membrane and spread of electrical excitation along the sarcolemma of cardiomyocytes.

The ubiquitous second messenger Ca^{2+} is the key player in cardiac ECC (see Fig. 14.12B).[25] Cycling of Ca^{2+} within the structures that participate in ECC initiates and terminates contraction. Activation of the contractile system depends on an increase in free cytosolic Ca^{2+} and its subsequent binding to contractile proteins.

Ca^{2+} enters through plasma membrane channels concentrated at the T tubules, and such entry through L-type Ca^{2+} channels (dihydropyridine receptors) triggers the release of Ca^{2+} from the SR.[28] This evokes a *Ca^{2+} spark*. Ca^{2+} sparks are considered to be the elementary Ca^{2+} signaling event of ECC in heart muscle. A Ca^{2+} spark occurs with the opening of a cluster of SR RyRs to release Ca^{2+} in a locally regenerative manner. It, in turn, activates the Ca^{2+}-release channels and induces further release of Ca^{2+} from subsarcolemmal cisternae in the SR and thus leads to a large increase in intracellular Ca^{2+} (iCa^{2+}). These spatially and temporally patterned activations of localized Ca^{2+} release, in turn, stimulate myofibrillar contraction. The increase in iCa^{2+}, however, is transient, inasmuch as Ca^{2+} is removed by active uptake by the SR Ca^{2+} pump adenosine triphosphatase (ATPase), extrusion of Ca^{2+} from the cytosol by the Na$^+$-Ca^{2+} exchanger, and binding of Ca^{2+} to proteins.[29] Ca^{2+} sparks have also been implicated in pathophysiologic diseases such as hypertension, cardiac arrhythmias, heart failure, and muscular dystrophy.[30-32]

The SR provides the anatomic framework and is the major organelle for the cycling of Ca^{2+}. It is the depot for iCa^{2+} stores. The cyclic release plus reuptake of Ca^{2+} by the SR regulates the cytosolic Ca^{2+} concentration and couples excitation to contraction. The physical proximity between L-type Ca^{2+} channels and RyRs at the SR membrane makes Ca^{2+}-induced Ca^{2+} release occur easily. The *foot* region of the RyR is the part that extends from the SR membrane to the T tubules, where the L-type Ca^{2+} channels are located.[19,29,33]

The SR is also concerned with the reuptake of Ca^{2+} that initiates relaxation or terminates contraction. The sarcoplasmic/endoplasmic reticulum Ca^{2+}-ATPase (SERCA) pump is the ATP-dependent pump that actively pumps the majority of the Ca^{2+} back into the SR after its release. SERCA makes up close to 90% of all the SR proteins and is inhibited by the phosphoprotein, phospholamban, at rest. Phospholamban is an SR membrane protein that is active in the dephosphorylated form. Phosphorylation by a variety of kinases as a result of β-adrenergic stimulation or other stimuli inactivates phospholamban and releases its inhibitory action on SERCA. Positive feedback ensues and leads to further phospholamban phosphorylation and greater SERCA activity. Active reuptake of Ca^{2+} by SERCA then promotes relaxation.[19,29,33]

Once taken up into the SR, Ca^{2+} is stored until it is released during the next cycle. Calsequestrin and calreticulin are two storage proteins in the SR. Calsequestrin is a highly charged protein located in the cisternal component of the SR near the T tubules. Because it lies close to the Ca^{2+}-release channels, the stored Ca^{2+} can be quickly discharged for release once the Ca^{2+}-release channels are stimulated. Cytosolic Ca^{2+} can also be removed by extrusion through the sarcolemmal Ca^{2+} pump and the activity of the Na$^+$-Ca^{2+} exchanger. The protein, calmodulin, is an important *sensor* and regulator of iCa^{2+}.[21]

Errors in Ca^{2+} Handling. Because of the ubiquity of Ca^{2+} in cardiac signaling, changes in Ca^{2+} handling can be associated with numerous maladaptive outcomes. There is an increase in Ca^{2+} leak from the SR in the failing heart, which may be associated with removal of Ca^{2+} from the cytosole.

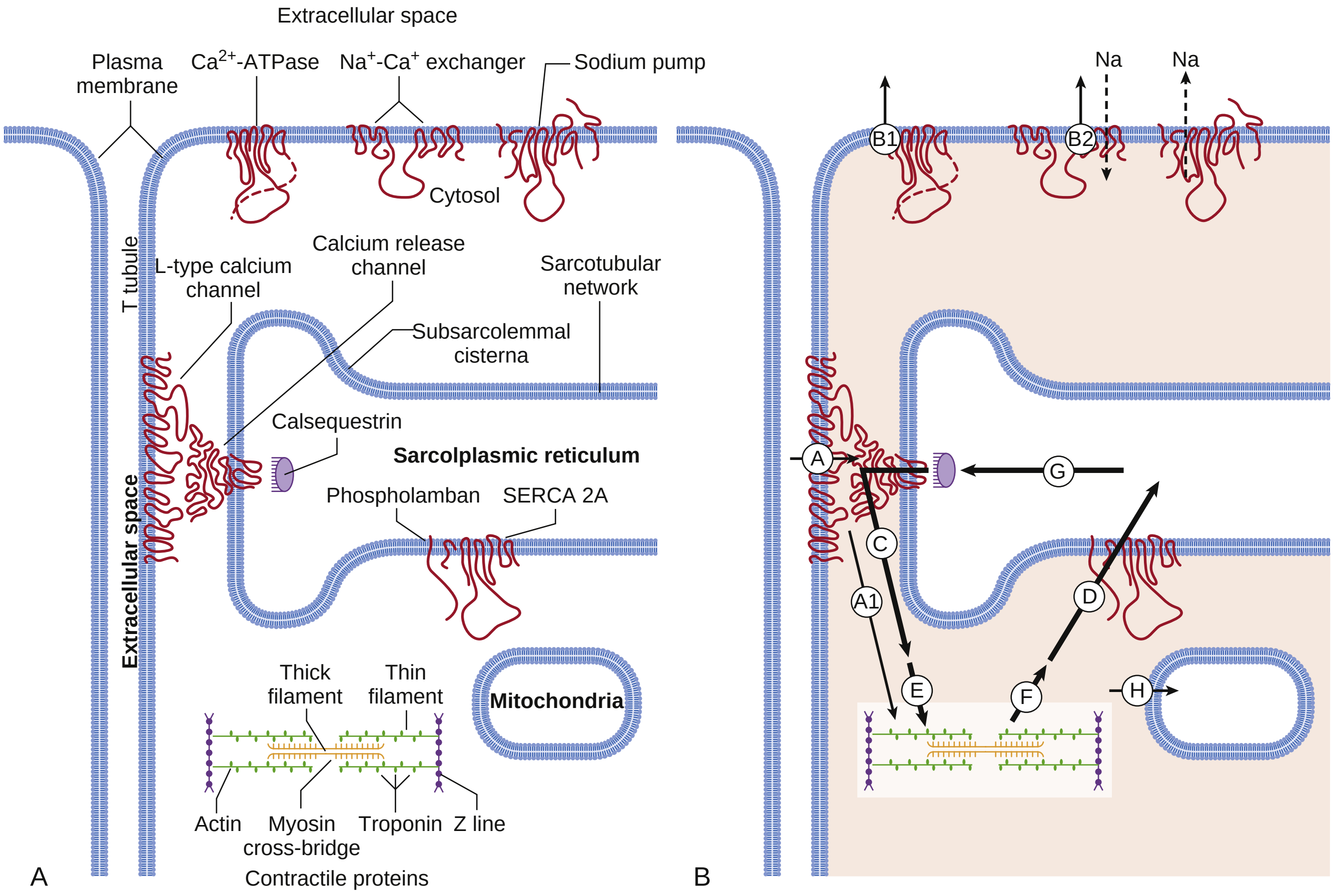

Fig. 14.12 (A) Diagram depicts the components of cardiac excitation-contraction coupling. Calcium pools are noted in **bold** letters. (B) Extracellular *(arrows A, B1, B2)* and intracellular calcium flux *(arrows C, D, E, F, G)* are shown. The thickness of the *arrows* indicates the magnitude of the calcium flux, and the vertical orientations describe their energetics: downward-pointing arrows represent passive calcium flux, whereas upward-pointing arrows represent energy-dependent calcium transport. Calcium entering the cell from extracellular fluid through L-type calcium channels triggers the release of calcium from the sarcoplasmic reticulum. Only a small portion directly activates the contractile proteins (*arrow A1*). Arrow B1 depicts active transport of calcium into extracellular fluid by means of the plasma membrane calcium adenosine triphosphatase (Ca^{2+}-ATPase) pump and the sodium-calcium (Na^{+}-Ca^{2+}) exchanger. Sodium that enters the cell in exchange for calcium *(dashed line)* is pumped out of the cytosol by the sodium pump. SR regulates calcium efflux from the subsarcolemmal cisternae *(arrow C)* and calcium uptake into the sarcotubular network *(arrow D)*. *Arrow G* represents calcium that diffuses within the SR. Calcium binding to *(arrow E)* and dissociation from *(arrow F)* high-affinity calcium-binding sites of troponin C activate and inhibit interactions of the contractile proteins. Arrow H depicts movement of calcium into and out of mitochondria to buffer the cytosolic calcium concentration. *SERCA 2A*, Sarcoplasmic/endoplasmic reticulum Ca^{2+}-ATPase. (From Katz AM. Calcium fluxes. In: *Physiology of the Heart*. 3rd ed. Philadelphia: Lippincott-Raven; 2001:232–233.)

This Ca^{2+} leak from the SR may significantly reduce contractile force in the heart and contributes to reduced inotropy in heart failure.[34,35] Uncoupling of β-AR activation of protein kinase A (PKA) and dysregulation of Ca^{2+} handling occurs in heart failure.[34] PKA, a cAMP-dependent protein kinase, is a key effector protein activated by β-AR agonists, which stimulates transsarcolemmal Ca^{2+} influx and its sequestration in the SR, leading to increased contractile function and lusitropy. Calcineurin, a Ca^{2+}-dependent signaling molecule, is consistently linked with myocardial hypertrophy via gene expression through a nuclear factor of activated T-cells pathway.[34,35] Calcium-calmodulin-dependent protein kinase II, in addition to calcineurin, is tightly coupled with Ca^{2+} homeostasis, and its prolonged activation can be proarrhythmic.

Contractile System

Contractile Elements. The basic working unit of contraction is the sarcomere. A *sarcomere* is defined as the distance between Z lines (Z is an abbreviation for the German word, *Zuckung*, meaning *contraction*), which join the sarcomeres in series. Each sarcomere consists of a central A band that is separated by one half of an I band from the Z lines on each side because the Z line bisects the I band. A schematic representation is depicted in Fig. 14.13.[10] Within each sarcomere are two principal contractile proteins (see the next section, Contractile Proteins) and one noncontractile protein, titin.[29] The two contractile proteins are actin, the thin filament, and myosin, the thick filament. Actin filaments and titin are both tethered to the Z line, but the thick myosin filaments do not actually reach the Z lines. Titin, the third filament protein, tethers the thick-filament myosin to the Z line. The Z lines at the two ends of the sarcomere are brought closer together during contraction as the thick-filament myosin heads interact with the thin actin filaments and slide over each other.[36,37]

Familial hypertrophic cardiomyopathy is an inherited autosomal dominant sarcomeric disease[38] that is the most common cause of sudden death in otherwise healthy individuals. Its clinical features are left ventricular hypertrophy

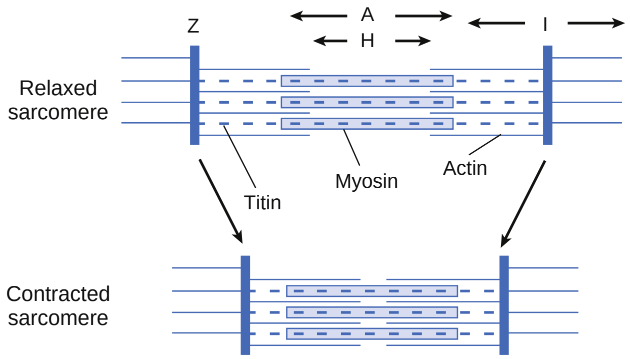

Fig. 14.13 The basic unit of contraction is the sarcomere. A contracted and relaxed sarcomere is depicted. Z lines are located at the ends of the sarcomere. The A band is the site of overlap between myosin and actin filaments. The I band is located on either side of the A band and contains only actin filament. The H zone is located in the center of the A band, and only myosin is present.

and myocyte and myofibrillar disarray. Mutations in at least eight different genes encoding sarcomere proteins have been identified as the molecular basis for the disorder. These genes are β-cardiac myosin heavy chain, cardiac troponin T (TnT), α-tropomyosin, cardiac myosin-binding protein C, essential or regulatory myosin light chain, cardiac troponin I (TnI), α-cardiac actin, and titin.[38]

Contractile Proteins. The contractile apparatus within the cardiomyocyte consists of contractile and regulatory proteins.[21,39,40] The thin-filament actin and the thick-filament myosin are the two principal contractile proteins. Actin contains two helical chains. Tropomyosin, a double-stranded α-helical regulatory protein, winds around the actin array and forms the backbone for the thin-filament actin. The thick-filament myosin is made up of 300 myosin molecules. Each myosin molecule has two functional domains: the body or filament and the bilobar myosin head. The myosin head is made up of one heavy chain and two light chains. The heavy head chain has two domains: the larger one interacts with actin at the actin cleft and has an ATP-binding pocket where myosin ATPase is located, and the other smaller one is flexible and attached to the two light chains. The regulatory troponin heterotrimer complex is found at regular intervals along tropomyosin. The heterotrimer troponins are made up of troponin C (TnC), the Ca^{2+} receptor; TnI, an inhibitor of actin-myosin interaction; and TnT, which links the troponin complex to tropomyosin. Tropomodulin is another regulatory protein. It is located at the end of the thin-filament actin and caps the end to prevent any excessive elongation of the thin filament.[36,37]

Myocyte Contraction and Relaxation. At rest, cross-bridge cycling and generation of force do not occur because either the myosin heads are blocked from physically reacting with the thin filament or they are only weakly bound to actin (Fig. 14.14).[18] Cross-bridge cycling is initiated on binding of Ca^{2+} to TnC, which increases TnC-TnI interaction and decreases the inhibitory TnI-actin interaction. These events, which ensue from the binding of Ca^{2+} to TnC, lead to conformational changes in tropomyosin and permit attachment of the myosin head to actin. Cross-bridging involves the detachment of the myosin head from actin and a reattachment of myosin to another actin on hydrolysis of ATP by myosin ATPase. Binding of ATP to the nucleotide pocket of the myosin head leads to the activation of myosin ATPase,[33,36,37] ATP hydrolysis, and changes in the configuration of the myosin head, all of which facilitate binding of the myosin head to actin and the generation of the power stroke of the myosin head. Based on this model, the rate of cross-bridge cycling is dependent on the activity of myosin ATPase.[40] Turnoff of cross-bridge cycling is largely initiated by the decrease in cytosolic Ca^{2+}.

Myocyte relaxation is an energy-dependent process because restoration of cytosolic Ca^{2+} to resting levels requires the expenditure of ATP. The decrease in cytosolic Ca^{2+} occurs through active reuptake of Ca^{2+} into the SR by SERCA and extrusion of Ca^{2+} by the Na^+-Ca^{2+} exchanger. This activity results in the release of Ca^{2+} binding to TnC and the separation of the myosin-actin cross-bridge. Myocyte relaxation is dependent on the kinetics of cross-bridge cycling, the affinity of Ca^{2+} for TnC, and the activity of the Ca^{2+}-reuptake mechanisms. Relaxation is enhanced by the increased kinetics of cross-bridge cycling, decreased Ca^{2+} affinity for TnC, and increased activity of Ca^{2+}-reuptake mechanisms.[29]

Titin is a giant string-like protein that acts as the third filament within the sarcomere. A single titin molecule spans one half of the sarcomere. Structurally, titin consists of an inextensible anchoring segment and an extensible elastic segment. Its two main functions involve muscle assembly and elasticity. Titin is the principal determinant of the passive properties of the myocardium at small ventricular volumes.[41]

The Frank-Starling relationship states that an increase in end-diastolic volume results in enhanced systolic function.[42,43] At the cellular level, the key component for the Frank-Starling relationship is a length-dependent shift in Ca^{2+} sensitivity.[44-46] Several possible mechanisms for this change in Ca^{2+} sensitivity have been implicated, including Ca^{2+} sensitivity: as a function of myofilament lattice spacing, involving positive cooperativity in cross-bridge binding to actin, and dependence on a strain of the elastic protein titin.[40,44]

Cytoskeleton Proteins. The cytoskeleton is the protein framework within the cytoplasm that links, anchors, or tethers structural components inside the cell.[18,21] Microfilaments (actin filaments), microtubules, and intermediate filaments are three classes of cytoskeleton proteins found in the cytoplasm. Microfilament proteins are actin filaments, either sarcomeric or cortical, depending on their location. Sarcomeric actin filaments are the thin filaments in the contractile machinery that have been previously described. Cortical actin filaments are found below the plasma membrane at the cell surface and are linked to several other microfilament proteins, including dystrophin, vinculin, and ankyrin. Microtubules assemble by polymerization of the α- and β-dimers of tubulin. They play a major role in intracellular transport and cell division.[47] Attachment of the ends of microtubules to cellular structures causes the microtubules to expand and contract, thereby pulling and pushing these structures around the cell. The intermediate filaments are relatively insoluble. They have been demonstrated to be important in normal mitochondrial function and behavior. The desmin intermediate filament in cardiomyocytes connects the nucleus to the plasma membrane and is important in the transmission of the stress and strain of contractile force between cells.[48]

The cytoskeleton provides the organization of microenvironments within the cell for enzyme and protein activity and interaction.

Whereas familial hypertrophic cardiomyopathy is a genetic sarcomeric disease, familial dilated cardiomyopathy (FDCM) is a disease of cytoskeleton proteins. The genetic basis of FDCM includes two genes for X-linked FDCM (dystrophin, G4.5) and four genes for the autosomal dominant form (actin, desmin, lamin A/C, and δ-sarcoglycan).[18]

Control of Cardiac Function

NEURAL REGULATION OF CARDIAC FUNCTION

The two limbs of the autonomic nervous system provide opposing input to regulate cardiac function.[49] The neurotransmitter of the sympathetic nervous system is norepinephrine, which provides positive chronotropic (heart rate), inotropic (contractility), and lusitropic (relaxation) effects. The parasympathetic nervous system has a more direct inhibitory effect in the atria and has a negative modulatory effect in the ventricles. The neurotransmitter of the parasympathetic nervous system is acetylcholine. Both norepinephrine and acetylcholine bind to seven-transmembrane-spanning G protein–coupled receptors (GPCRs) to transduce their intracellular signals and affect their functional responses (Fig. 14.15).[50] At rest, the heart has a tonic level of parasympathetic cardiac nerve firing and little, if any, sympathetic activity. Therefore, the major influence on the heart at rest is parasympathetic. During exercise or stress, however, the sympathetic neural influence becomes more prominent.

Parasympathetic innervation of the heart is through the vagal nerve. Supraventricular tissue receives significantly more intense vagal innervation than do the ventricles. The principal parasympathetic target neuroeffectors are the muscarinic receptors in the heart.[51,52] Activation of muscarinic receptors reduces pacemaker activity, slows AV conduction, directly decreases atrial contractile force, and exerts inhibitory modulation of ventricular contractile force. A total of five muscarinic receptors have been cloned.[53] M_2 receptors are the predominant subtype found in the mammalian heart. In the coronary circulation, M_3 receptors have been identified. Moreover, non-M_2 receptors have also been reported to exist in the heart. In general, for intracellular signaling, M_1, M_3, and M_5 receptors couple to $G_{q/11}$ protein and activate the phospholipase C-diacylglycerol-inositol phosphate system. On the other hand, the M_2 and M_4 receptors couple to the pertussis toxin-sensitive G protein, $G_{i/o}$, to inhibit adenylyl cyclase. M_2 receptors can couple to certain K^+ channels and influence the activity of Ca^{2+} channels, I_f current, phospholipase A_2, phospholipase D, and tyrosine kinases.

In contrast to vagal innervation, sympathetic innervation of the heart is more predominant in the ventricle than in the atrium. Norepinephrine released from sympathetic nerve terminals stimulates adrenergic receptors (adrenoreceptors [AdRs]) located in the heart. The two major classes of ARs are α and β, both of which are GPCRs that transduce their intracellular signals by means of specific signaling cascades (Fig. 14.16).

β-ARs can be further divided into subpopulations of β_1, β_2, and β_3.[54] Although most mammalian hearts contain β1-ARs and β_2-ARs, β_3-ARs also exist in many mammalian ventricular tissues. The relative contribution of each β-AR subtype to modulation of cardiac function varies among species. In humans, β_1-ARs are the predominant subtype in both the atria and ventricles, but a substantial proportion of β_2-ARs are found in the atria, and approximately 20% of β_2-ARs are found in the LV. Much less is known about β_3-ARs, but they do exist in the human ventricle. Even though the β_1-AR population is more intense than the β_2-AR population, the cardiostimulant effect is not proportional to the relative densities of these two subpopulations, which is largely attributable to the tighter coupling of β_2-ARs than β_1-ARs to the cyclic adenosine monophosphate (cAMP) signaling pathway. Both β_1-ARs and β_2-ARs activate a pathway that involves the stimulatory G protein (Gs), activation of adenylyl cyclase, accumulation of cAMP, stimulation of cAMP-dependent PKA, and phosphorylation of key target proteins, including L-type Ca^{2+} channels, phospholamban, and TnI.

Both β_1-ARs and β_2-ARs are coupled to the G_s-cAMP pathway. Additionally, β_2-ARs can couple to G protein–independent pathways to modulate cardiac function, and also couple to the inhibitory G protein (Gi) to activate non–cAMP-dependent signaling pathways. β-AR stimulation increases both contraction and relaxation, as summarized in Fig. 14.17.

The two major subpopulations of α-ARs are α_1 and α_2. α_1-ARs and α_2-ARs can be further subdivided into different subtypes. α_1-ARs are GPCRs and include the α_{1A}, α_{1B}, and α_{1D} subtypes. The α_1-AR subtypes are products of separate genes and differ in structure, G protein coupling, tissue distribution, signaling, regulation, and function. Both

α_{1A}-ARs and α_{1B}-ARs mediate positive inotropic responses. However, the positive inotropic effect mediated by α_1-ARs is believed to be of minor importance in the heart. α_1-ARs are coupled to phospholipase C, phospholipase D, and phospholipase A_2; they increase iCa^{2+} and myofibrillar sensitivity to Ca^{2+}.

Cardiac hypertrophy is primarily mediated by α_{1A}-ARs.[55,56] Cardiac hypertrophic responses to α_1-AR agonists involve activation of protein kinase C and mitogen-activated protein kinase through G_q-signaling mechanisms. Three subtypes of α_2-ARs are recognized: α_{2A}, α_{2B}, and α_{2C}. In the mammalian heart, α_2-ARs in the atrium play a role in the presynaptic inhibition of norepinephrine release. These prejunctional α_2-ARs are believed to belong to the α_{2C} subtype.

Neural regulation of cardiac function involves a complex interaction between the different classes and subpopulations of adrenoceptors and their signaling pathways. Targeted therapeutics in cardiovascular medicine involve the clinical application and manipulation of a basic understanding of adrenoceptor pharmacology.

HORMONES AFFECTING CARDIAC FUNCTION

Many hormones have direct and indirect actions on the heart (Table 14.1). Hormones with cardiac actions can be synthesized and secreted by cardiomyocytes or produced by other tissues and delivered to the heart. They act on specific receptors expressed in cardiomyocytes. Most of these hormone receptors are plasma membrane GPCRs. Non-GPCRs include the natriuretic peptide receptors, which are guanylyl cyclase-coupled receptors, and the glucocorticoid and mineralocorticoid receptors, which bind androgens and aldosterone and are nuclear zinc finger transcription factors. Hormones can have activity in normal cardiac physiologic function or are active only in pathophysiologic conditions, or both situations can apply. Most of the new information regarding the action of hormones in the heart has been derived from the endocrine changes associated with chronic heart failure.[57]

Cardiac hormones are polypeptides secreted by cardiac tissues into the circulation in the normal heart. Natriuretic peptides,[58,59] aldosterone,[60] and adrenomedullin[61] are hormones secreted by cardiomyocytes. Angiotensin II, the effector hormone in the renin-angiotensin system, is also produced by cardiomyocytes.[62,63] The renin-angiotensin system is one of the most important regulators of cardiovascular physiology. It is a key modulator of cardiac growth and function. Angiotensin II stimulates two separate receptor subtypes, AT_1 and AT_2, both of which are present in the heart. AT_1 receptors are the predominant subtype expressed in the normal adult human heart. Stimulation of AT_1 receptors induces a positive chronotropic and inotropic effect. Angiotensin II also mediates cell growth and proliferation in cardiomyocytes and fibroblasts, and induces the release of the growth factors aldosterone and catecholamines through the stimulation of AT_1 receptors. Activation of AT_1 receptors is directly involved in the development of cardiac hypertrophy and heart failure, as well as adverse remodeling of the myocardium. In contrast, AT_2 receptor activation is counterregulatory and generally antiproliferative. Expression of AT_2 receptors, however, is relatively scant in the adult heart because AT_2 receptors are most abundant in the fetal heart and decline with development. In response to injury and ischemia, AT_2 receptors become upregulated. The precise role of AT_2 receptors in the heart remains to be defined.

The beneficial effects of blockade of the renin-angiotensin system with angiotensin-converting enzyme inhibitors in the treatment of heart failure have been attributed to an inhibition of AT_1-receptor activity. In addition to the renin-angiotensin system, other cardiac hormones that have been shown to play pathogenic roles in the promotion of cardiomyocyte growth and cardiac fibrosis, development of cardiac hypertrophy, and progression of congestive heart failure include aldosterone,[60] adrenomedullin,[64-66] natriuretic peptides,[58,59] angiotensin,[67-69] endothelin,[70] and vasopressin.[71,72]

Increased stretch of the myocardium stimulates the release of atrial natriuretic protein (ANP) and B-type natriuretic protein (BNP) from the atria and ventricles, respectively. Both ANP and BNP bind to natriuretic peptide receptors to generate the second messenger cyclic guanosine monophosphate and represent part of the cardiac

endocrine response to hemodynamic changes caused by pressure or volume overload. They also participate in organogenesis of the embryonic heart and cardiovascular system.[58,59] In patients with chronic heart failure, increases of serum ANP and BNP levels are a predictor of mortality.[73]

Adrenomedullin is a recently discovered cardiac hormone that was originally isolated from pheochromocytoma tissue. It increases the accumulation of cAMP and has direct positive chronotropic and inotropic effects.[61,64,65] Adrenomedullin, with interspecies and regional variations, has also been shown to increase nitric oxide production, and it functions as a potent vasodilator.

Aldosterone is one of the cardiac-generated steroids, although its physiologic significance remains to be defined. It binds to mineralocorticoid receptors and can increase the expression or activity (or both) of cardiac proteins involved in ionic homeostasis or the regulation of pH, such as cardiac Na^+/K^+-ATPase, the Na^+-K^+ cotransporter, Cl^--bicarbonate (HCO_3^{2+}), and the Na^+-hydrogen (H^+) antiporter.[60] Aldosterone modifies cardiac structure by inducing cardiac fibrosis in both ventricular chambers and thereby leads to impairment of cardiac contractile function.

Other hormones such as the growth hormone,[74] thyroid hormones,[75] and sex steroid hormones (see the following text) can also have cardiac effects through direct actions of nuclear receptors or indirect effects.

Sex Steroid Hormones and the Heart

Cardiac contractility is more intense in premenopausal women than in age-matched men, and withdrawal of hormone replacement therapy in postmenopausal women leads to a reduction in cardiac contractile function. The gender dimorphism in heart function and its adaptive responses to injury and disease states are partly mediated by sex steroid hormones. Indeed, healthy premenopausal women exhibit a lower cardiovascular risk compared to men, which suggests a mechanism for sex hormones in the modulation of cardiac function.[76]

The most extensively studied sex steroid hormones are estradiol-17β (E2) and its bioactive metabolites. They bind and act on the two subtypes of estrogen receptors (ERs) in the heart: ERα and ERβ. Progesterone and testosterone (two other sex steroid hormones) and the enzyme aromatase, which converts testosterone to estrogen, are much less well investigated. Progesterone and testosterone bind and act on their respective progesterone receptors and androgen receptors in the heart. Sex steroid hormones interact with their receptors to affect postsynaptic target cell responses and to influence presynaptic sympathoadrenergic function. Cardiomyocytes are not only targets for the action of sex steroid hormones, but they are also the source of synthesis and the site of metabolism of these hormones.[77]

E2 is derived from testosterone and is primarily metabolized in the liver to form hydroxyestradiols, catecholestradiols, and methoxyestradiols. Estradiol metabolism also takes place in vascular smooth muscle cells, cardiac fibroblasts, endothelial cells, and cardiomyocytes. Cardiomyocytes express nuclear steroid hormone receptors that modulate gene expression and nonnuclear receptors for the nongenomic effects of sex steroid hormones. They interact with

many different coregulators to confer tissue and temporal specificity in their transcriptional actions. These cell-specific coactivator and corepressor proteins are known as estrogen-related receptors.[78] Sex steroid hormones can activate rapid signaling pathways without changing gene expression (Fig. 14.18). One such example is stimulation of vascular endothelial nitric oxide synthase to mediate vascular dilation. Estrogen's vasodilatory effect might explain the lower systolic blood pressures of premenopausal women when compared with age-matched men. In men, aromatase-mediated conversion of testosterone to estrogen maintains normal vascular tone. In addition to sex steroid hormone stimulation of nuclear or nonnuclear receptors, sex steroid hormone receptors could also induce rapid signaling of growth factor pathways in the absence of ligands.

Gender differences exist in cardiac electrophysiologic function. The modulatory actions of estrogen on Ca^{2+} channels might be responsible for sex-based differences in repolarization of the heart, such as the faster resting heart rate of women, as well as the increased propensity of women to have prolonged QT syndrome.[79] Estrogen, through the activation of ERβ, confers protection after ischemia and reperfusion in murine models of myocardial infarction. In contrast, testosterone, in the same model, has the opposite effect. Aromatase also has protective effects, probably through its action to increase estrogen and to decrease testosterone.

Gender differences in cardiac physiology should include consideration of the cellular physiology of sex steroid hormones in males and females; intrinsic differences in the physiology of cardiomyocytes, vascular smooth muscle cells, and endothelial cells between males and females; and gender-based differences in the autonomic modulation of cardiac physiology.

CARDIAC REFLEXES

Cardiac reflexes are fast-acting reflex loops between the heart and the central nervous system (CNS) that contribute to regulation of cardiac function and the maintenance of physiologic homeostasis. Specific cardiac receptors elicit their physiologic responses by various pathways. Cardiac receptors are linked to the CNS by myelinated or unmyelinated afferent fibers that travel along the vagus nerve. Cardiac receptors are in the atria, ventricles, pericardium, and coronary arteries. Extracardiac receptors are located in the great vessels and carotid artery. Sympathetic and parasympathetic nerve input is processed in the CNS. After central processing, efferent fibers to the heart or the systemic circulation will provoke a specific reaction. The response of the cardiovascular system to efferent stimulation varies with age and duration of the underlying condition that elicited the reflex in the first instance.

Baroreceptor Reflex (Carotid Sinus Reflex)

The baroreceptor reflex is responsible for the maintenance of arterial blood pressure. This reflex regulates arterial pressure around a preset value through a negative-feedback loop (Fig. 14.19).[80,81] In addition, the baroreceptor reflex is capable of establishing a prevailing set point for arterial blood pressure when the preset value has been reset because of chronic hypertension. Changes in arterial blood pressure are monitored by circumferential and longitudinal stretch

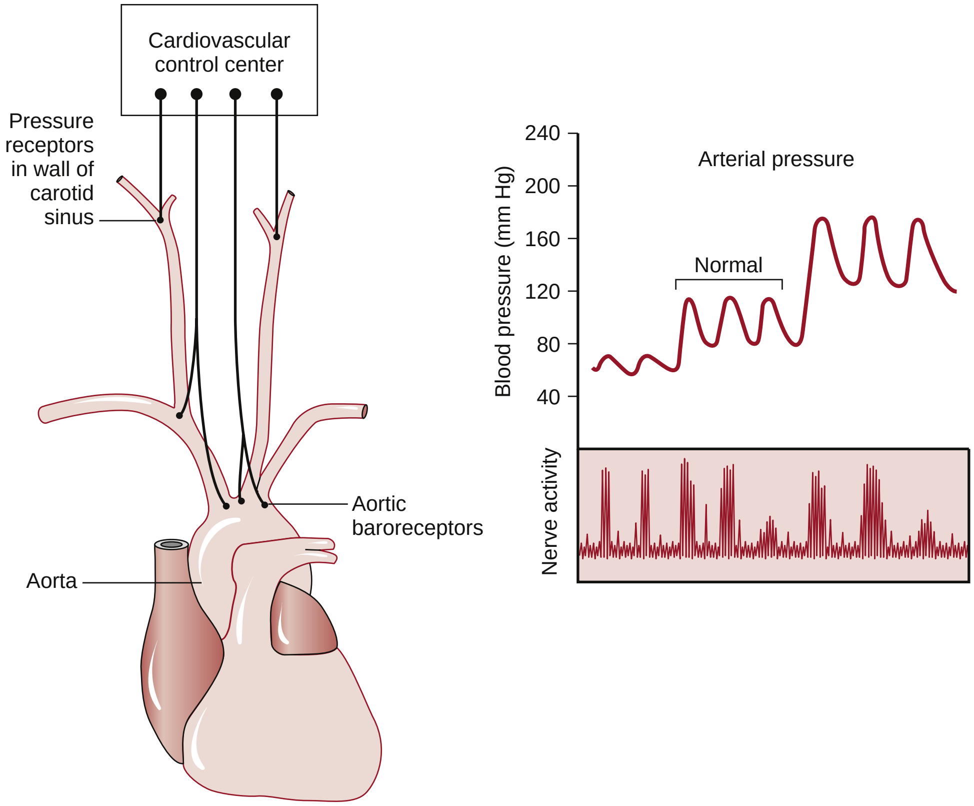

Fig. 14.19 Anatomic configuration of the baroreceptor reflex. Pressure receptors in the wall of the carotid sinuses and aorta detect changes in arterial pressure in the circulation. These signals are conveyed to afferent receptive regions of the medulla through the Hering and vagus nerves. Output from effector portions of the medulla modulates peripheral tone and heart rate. The increase in blood pressure results in increased activation of the reflex *(right)*, which affects a decrease in blood pressure. (From Campagna JA, Carter C. Clinical relevance of the Bezold-Jarisch reflex. *Anesthesiology.* 2003;98:1250–1260.)

receptors located in the carotid sinus and aortic arch. The nucleus solitarius, located in the cardiovascular center of the medulla, receives impulses from these stretch receptors through afferents of the glossopharyngeal and vagus nerves. The cardiovascular center in the medulla consists of two functionally different areas; the area responsible for increasing blood pressure is laterally and rostrally located, whereas the area responsible for lowering arterial blood pressure is centrally and caudally located. The latter area also integrates impulses from the hypothalamus and the limbic system. Typically, stretch receptors are activated if systemic blood pressure is greater than 170 mm Hg. The response of the depressor system includes decreased sympathetic activity, leading to a decrease in cardiac contractility, heart rate, and vascular tone. In addition, activation of the parasympathetic system further decreases the heart rate and myocardial contractility. Reverse effects are elicited with the onset of hypotension.

The baroreceptor reflex plays an important beneficial role during acute blood loss and shock. However, the reflex arch loses its functional capacity when arterial blood pressure is less than 50 mm Hg. Hormonal status and therefore sex differences may alter baroreceptor responses.[82] Furthermore, volatile anesthetics (particularly halothane) inhibit the heart rate component of this reflex.[83] Concomitant use of Ca^{2+}-channel blockers, angiotensin-converting enzyme inhibitors, or phosphodiesterase inhibitors will lessen the cardiovascular response of raising blood pressure through the baroreceptor reflex. This lessened response is achieved by either their direct effects on the peripheral vasculature or, more importantly, their interference with CNS signaling pathways (Ca^{2+}, angiotensin).[84] Patients with chronic hypertension often exhibit perioperative circulatory instability as a result of a decrease in their baroreceptor reflex response.

Chemoreceptor Reflex

Chemosensitive cells are located in the carotid bodies and the aortic body. These cells respond to changes in pH status and blood O_2 tension. At an arterial partial O_2 pressure (PaO_2) of less than 50 mm Hg or in conditions of acidosis, the chemoreceptors send their impulses along the sinus nerve of Hering (a branch of the glossopharyngeal nerve) and the tenth cranial nerve to the chemosensitive area of the medulla. This area responds by stimulating the respiratory centers and thereby increasing ventilatory drive. In addition, activation of the parasympathetic system ensues and leads to a reduction in heart rate and myocardial contractility. In the case of persistent hypoxia, the CNS will be directly stimulated, with a resultant increase in sympathetic activity.

Bainbridge Reflex

The Bainbridge reflex[85-87] is elicited by stretch receptors located in the right atrial wall and the cavoatrial junction. An increase in right-sided filling pressure sends vagal afferent signals to the cardiovascular center in the medulla. These afferent signals inhibit parasympathetic activity, thereby increasing the heart rate. Acceleration of the heart rate also results from a direct effect on the SA node by stretching the atrium. The changes in heart rate are dependent on the underlying heart rate before stimulation.

Bezold-Jarisch Reflex

The Bezold-Jarisch reflex responds to noxious ventricular stimuli sensed by chemoreceptors and mechanoreceptors within the left ventricular wall by inducing the triad of hypotension, bradycardia, and coronary artery dilatation.[80] The activated receptors communicate along unmyelinated vagal afferent type C fibers. These fibers reflexively increase parasympathetic tone. Because it invokes bradycardia, the Bezold-Jarisch reflex is thought of as a cardioprotective reflex. This reflex has been implicated in the physiologic response to a range of cardiovascular conditions such as myocardial ischemia or infarction, thrombolysis, or revascularization and syncope. Natriuretic peptide receptors stimulated by endogenous ANP or BNP may modulate the Bezold-Jarisch reflex. Thus, the Bezold-Jarisch reflex may be less pronounced in patients with cardiac hypertrophy or atrial fibrillation.[88]

Valsalva Maneuver

Forced expiration against a closed glottis produces increased intrathoracic pressure, increased central venous pressure, and decreased venous return. Cardiac output and blood pressure will be decreased after the Valsalva maneuver. This decrease will be sensed by baroreceptors and will reflexively result in an increase in heart rate and myocardial contractility through sympathetic stimulation. When the glottis opens, venous return increases and causes the heart to respond by vigorous contraction and an increase in blood pressure. This increase in arterial blood pressure will, in turn, be sensed by baroreceptors, thereby stimulating the parasympathetic efferent pathways to the heart.

Cushing Reflex

The Cushing reflex is a result of cerebral ischemia caused by increased intracranial pressure. Cerebral ischemia at the medullary vasomotor center induces initial activation of the sympathetic nervous system. Such activation will lead to an increase in heart rate, arterial blood pressure, and myocardial contractility in an effort to improve cerebral perfusion. As a result of the high vascular tone, reflex bradycardia mediated by baroreceptors will ensue.

Oculocardiac Reflex

The oculocardiac reflex is provoked by pressure applied to the globe of the eye or traction on the surrounding structures. Stretch receptors are located in the extraocular muscles. Once activated, stretch receptors will send afferent signals through the short- and long-ciliary nerves. The ciliary nerves will merge with the ophthalmic division of the trigeminal nerve at the ciliary ganglion. The trigeminal nerve will carry these impulses to the gasserian ganglion, thereby resulting in increased parasympathetic tone and subsequent bradycardia. The incidence of this reflex during ophthalmic surgery ranges from 30% to 90%. Administration of an antimuscarinic drug such as glycopyrrolate or atropine reduces the incidence of bradycardia during eye surgery.

Acknowledgment

The editors, publisher, and Dr. Lena Sun would like to thank Drs. Johanna Schwarzenberger and Radhika Dinavahi for their contribution to this chapter in the prior edition of this work. It has served as the foundation for the current chapter.

Gastrointestinal Physiology and Pathophysiology

LAURIE O. MARK and A. SASSAN SABOURI

KEY POINTS

- The gastrointestinal (GI) tract forms a long tube from mouth to anus and its main functions are motility, digestion, absorption, excretion, and circulation. Each component of the GI tract has specific functions.
- The layers of the GI tract wall are (outermost to innermost): serosa, longitudinal muscle, circular muscle, submucosa, and mucosa. Within the mucosa is (outermost to innermost): muscularis mucosae, lamina propria, and epithelium.
- The GI tract is innervated by the autonomic nervous system. The extrinsic nervous system consists of the sympathetic, which is primarily inhibitory, and parasympathetic, which is primarily excitatory on GI tract motility. The enteric nervous system controls motility, secretion, and blood flow.
- Mixing movements and propulsive movements are the two primary movements within and along the GI tract. The mechanisms for each are altered significantly in the diseased state and there are multiple modalities for evaluating these alterations.
- The effect of general anesthesia on the GI tract is multifaceted and everything from the medications administered to the hemodynamic side effects can alter GI tract function. Opioids, in particular, have an adverse effect on the bowel and there are many efforts underway to decrease the use of opioids in GI surgery.
- Hemodynamic changes, bowel manipulation, and open abdominal surgeries can produce major effects on the anatomy and function of the GI tract including postoperative ileus, inflammatory states, mesenteric ischemia, and partial or total disruption of myogenic continuity.
- The innervation of the GI organs up to the proximal transverse colon is supplied by the celiac plexus, whereas the innervation of the descending colon and distal GI tract comes from the inferior hypogastric plexus.
- The celiac plexus can be blocked via different approaches, including: transcrural, intraoperative, endoscopic ultrasound-guided, and peritoneal lavage.
- Epidural anesthesia can suppress sympathetic mediated GI reflexes and reduce the incidence of postoperative ileus.
- Pain management strategies that use regional anesthetic techniques and avoid the use of systemic opioids help reduce the incidence of postoperative nausea and vomiting.
- The Enhanced Recovery after GI Surgery (ERAS) protocol and evidence-based practices helps to preserve natural GI physiology and is associated with shorter hospitalizations.
- The ERAS protocol focuses on: optimal perioperative pain control; nutrition; avoidance of unnecessary tubes, lines, and drains; temperature; fluid management; and early ambulation.

Introduction

The purpose of this chapter is to gain an understanding of the various components of gastrointestinal (GI) anatomy and their respective functions. This understanding of the GI system in the healthy state will pave the way for an understanding of how it is affected in different and common disease states. The chapter then transitions into a discussion of perioperative considerations for the anesthetist, including the effects of various anesthetic medications and surgical conditions on bowel function and physiology. The remainder of the chapter will focus on gastrointestinal innervation and how various regional anesthesia and pain management strategies are used when dealing with GI conditions and surgeries.

Gastrointestinal Anatomy and Function

The GI tract constitutes approximately 5% of the total human body mass. Its main functions are motility, digestion, absorption, excretion, and circulation. This section is composed of two parts. In the first part, the basic anatomy and innervation common to all parts of the GI tract are discussed. In the second part the specific anatomy and function of the esophagus, stomach, small bowel, and large bowel are discussed. The pancreas, liver, and biliary tract are covered in Chapter 16.

Common to all parts of the GI tract are the layers of the wall, but the functions of each layer differ from organ to organ.

From outermost to innermost these layers are the serosa, longitudinal muscle layer, circular muscle layer, submucosa, and mucosa. Within the mucosa is (outermost to innermost) the muscularis mucosae, lamina propria, and epithelium. The serosa is a smooth membrane of thin connective tissue and cells that secrete serous fluid that serves to enclose the cavity and reduce friction between muscle movements. The longitudinal muscle layer contracts in order to shorten the length of the intestinal segment whereas the circular muscle layer contracts to decrease the diameter of the intestinal lumen. These two layers work together to allow for gut motility. Between these smooth muscle layers is the myenteric (Auerbach) plexus, which regulates the gut smooth muscle. The submucosa contains the submucosal (Meissner) plexus, which transmits information from the epithelium to the enteric and central nervous systems (CNS). The mucosa is composed of a thin layer of smooth muscle called the muscularis mucosa, which functions to move the villi; the lamina propria, which contains blood vessels, nerve endings, and immune and inflammatory cells; and the epithelium, which is where the GI contents are sensed and where secretion of enzymes, absorption of nutrients, and excretion of waste products occur.

The GI tract is innervated by the autonomic nervous system. This is composed of the extrinsic nervous system, which has sympathetic and parasympathetic components, and the enteric nervous system. The extrinsic sympathetic nervous system is primarily inhibitory as stimulation can decrease or cease GI motility. The preganglionic fibers originate at the T5 to L2 segments of the spinal cord. They travel to the sympathetic chain of ganglia and synapse with postganglionic neurons. Then they travel to the gut where they terminate at the enteric nervous system. The primary neurotransmitter is norepinephrine. Vasoactive intestinal polypeptide (VIP) also transmits sympathetic signals. The extrinsic parasympathetic nervous system is primarily excitatory as it activates GI motility and function. Parasympathetic preganglionic fibers originate in the medulla and sacral region of the spinal cord. Vagus nerve fibers innervate the esophagus, stomach, pancreas, small intestine, and the first half of the large intestine. Pelvic nerve fibers innervate the second half of the large intestine, sigmoid, rectal, and anal regions. The primary neurotransmitter is acetylcholine.

The enteric nervous system is the independent nervous system of the GI tract, which controls motility, secretion, and blood flow. Two plexuses constitute the enteric nervous system: the myenteric (Auerbach) plexus and the submucosal (Meissner) plexus. The myenteric plexus controls motility, which is carried out by enteric neurons, interstitial cells of Cajal (pacemaker cells that generate intrinsic electrical activity of the GI tract), and smooth muscle cells. The submucosal plexus controls absorption, secretion, and mucosal blood flow. Both of these plexuses respond to sympathetic and parasympathetic stimulation. Sympathetic stimulation is inhibitory so it will increase the tone of the intestinal wall whereas parasympathetic stimulation is excitatory and will induce intestinal contractions and movement. Additionally, there are a variety of reflexes in the enteric nervous system. For example, when there is sympathetic stimulation the tone of the wall increases, the sphincters contract, and, reflexively, the amount of excitatory acetylcholine released is reduced. The mechanism is via α-2 activation, which inhibits the release of acetylcholine and through β activation which contracts sphincter muscles and relaxes intestinal muscles. These two actions work together to slow the transit of contents through the GI tract.

This next section serves to briefly discuss the anatomy and function of the various components of the GI tract. Only the esophagus, stomach, small intestine, and large intestine are covered. See Table 15.1 for an overview of GI tract anatomy and function.

The esophagus is a muscular tube that connects the pharynx to the stomach. It is the first passageway for food entry into the digestive system. It is approximately 18 to 25 cm in length and extends from the level of the hypopharynx at the C6 vertebrae down to the gastroesophageal (GE) junction at the T11 level.[1] The esophagus has three regions: cervical, thoracic, and abdominal. The cervical esophagus is approximately 4 to 5 cm long and is surrounded by the trachea anteriorly, the vertebral column posteriorly, and the carotid sheaths and thyroid gland laterally. The thoracic esophagus spans from the suprasternal notch to the diaphragmatic hiatus and lies posterior to the trachea. At the level of the carina, it deviates right to allow room for the aortic arch and runs posteriorly and underneath the left mainstem bronchus. From T8 to the diaphragmatic hiatus (T10) the esophagus runs anterior to the aorta. The abdominal esophagus extends from the diaphragmatic hiatus to the cardia of the stomach. The upper one-third of the esophagus is composed of striated muscle and the remaining two-thirds is smooth muscle. There are two areas of high pressure: the upper esophageal sphincter (UES) and the lower esophageal sphincter (LES). The UES lies at the level of the cricoid cartilage and is made up of the cricopharyngeal, inferior constrictor, and circular esophageal muscles. Resting tone ranges from 30–200 mm Hg. Opening and closing of the UES is coordinated with the pharyngeal pushing of food downstream. The LES is formed intrinsically by circular esophageal muscle and extrinsically by the diaphragm muscle. It has both sympathetic and parasympathetic innervation. Resting tone is 10–45 mm Hg.[2]

The stomach is a J-shaped dilation of the alimentary tract. It is divided into four regions: the cardia, fundus, body or corpus, and antrum. The stomach has three main functions: store large quantities of food (up to 1.5–2 liters), mix food with gastric secretions to form chyme and break down particle size, and slow emptying into the small intestine. The proximal stomach is the reservoir for undigested food and produces smooth, tonic contractions. The distal stomach grinds, mixes, and sieves food particles via high-amplitude contractions. Notable cell types in the stomach that aid in digestion are the mucous cells, which protect against harsh hydrochloric acid; parietal cells, which secrete hydrochloric acid; chief cells, which secrete pepsin; and G cells, which secrete gastrin. Together these cells' secretions break down and partially digest the food into chyme as well as reduce particle dimension to an appropriate size (2 mm or less) before it enters the small intestine.[2]

TABLE 15.1 Table of Gastrointestinal Components, Locations, and Functions

Component	Location	Function
Esophagus	Extends from C6 to T11	Propels food from the pharynx to the stomach
Stomach	Left upper abdominal cavity. Diaphragm along the top, pancreas posteriorly, greater omentum laterally	Receives food from the esophagus and initiates digestion. Breaks down food into chyme through physical and chemical mechanisms
Duodenum	Inferior to stomach, approximately 25–30 cm long	Chemically digests chyme for absorption in the small intestine
Jejunum	Between duodenum and ileum	Absorption of nutrients from chyme
Ileum	Between jejunum and cecum	Further nutrient absorption
Cecum	Lower right quadrant of abdominal cavity, inferior and lateral to the ileum	A space for mixing of chyme with bacteria to form fecal matter
Ascending colon	Runs superiorly from the cecum to the right inferior border of the liver where it turns 90 degrees to become the transverse colon	Peristaltic waves move the feces superiorly where bacteria digest the waste and further nutrients, water, and vitamins are absorbed
Transverse colon	Crosses abdominal cavity right to left just below the stomach	Fecal formation
Descending colon	Runs inferiorly along the left side of the abdominal cavity	Stores fecal matter prior to elimination. Further absorbs water, nutrients, vitamins
Sigmoid colon	Lower left quadrant of the abdominal cavity	Stores fecal matter prior to elimination
Rectum	Posterior pelvic cavity. Along the anterior surface of the sacrum and coccyx	Stores fecal matter prior to elimination. Distention will activate stretch receptors allowing the internal anal sphincter to relax and allow for defecation.

The duodenum is the first and smallest section of the small intestine. It is between 25 and 30 cm long and it forms a C-shaped loop around the pancreas. Its main function is to chemically digest the chyme received from the stomach in preparation for absorption. The pancreas, liver, and gallbladder secrete digestive enzymes through the ampulla of Vater into the middle portion of the duodenum.[2]

The jejunum is the second section of the small intestine and its primary function is to absorb nutrients. The digested chyme from the duodenum enters the jejunum where it is mixed and circulated for exposure to the jejunal walls for nutrient absorption. The walls of the jejunum are folded many times over to increase its surface area and allow for maximal absorption of nutrients. By the time chyme enters the ileum, almost 90% of all available nutrients are absorbed.[2]

The ileum is the final section of the small intestine. It serves to absorb vitamin B12 and other products of digestion that were not previously absorbed in the jejunum. It ends at the ileocecal valve—a circular muscle that serves to prevent reflux of colonic contents into the small intestine. It contracts in response to colonic dilation and relaxes in response to ileal dilation.[2]

The large intestine is composed of the cecum, appendix, ascending colon, transverse colon, descending colon, sigmoid colon, and rectum. Briefly, the cecum is a pouch at the beginning of the large intestine that allows for mixing of the chyme from the small intestine with bacteria to form fecal matter. The ascending colon transports the fecal matter superiorly along the right side up to the transverse colon. Along the way the ascending colonic wall absorbs water, nutrients, and vitamins. The transverse colon, the longest portion of the large intestine, crosses the abdominal cavity. Its contractions serve to mix the feces and allow bacteria to ferment the waste. Further absorption of water and nutrients also take place. The feces then enter the descending colon, which stores the feces until it is ready for transport, inferiorly and along the left side of the abdominal cavity to the sigmoid colon. Again, the walls of the descending colon allow for further absorption of water and nutrients. The sigmoid colon is an S-shaped, curved region that stores then transports fecal matter from the descending colon to the rectum and anus for elimination. The final portion of the large intestine is the rectum where feces are stored until elimination. As fecal matter accumulates it exerts pressure on the walls of the rectum. This activates stretch receptors and leads to relaxation of the internal anal sphincter allowing for elimination.[2]

Transit Time in Health and Disease

This section serves to discuss motility in the esophagus, stomach, small intestine, and large intestine. Emphasis is placed on mechanism, how motility and transit are altered by various disease states, and methods for evaluating motility.

Mixing movements and propulsive movements are the two primary movements within and along the GI tract. Mixing movements keep the contents of the intestine appropriately and thoroughly mixed throughout, while the propulsive movements, consisting of periodic contractions of certain GI tract segments (peristalsis), move the contents of the intestine along the tract.

Transit through the esophagus starts with swallowing. Swallowing starts with the oropharynx pushing food backward and downward while the muscles of the nasopharynx prevent food from entering the nasal passages. When ready to be swallowed the food is squeezed and rolled into the posterior pharynx by the tongue. The epiglottis moves upward in a protective mechanism over the larynx and trachea to prevent aspiration. The act of swallowing inhibits the respiratory center to protect from aspiration but it is so short-lived it is unnoticeable. Food enters the esophagus through the UES, which then constricts to prevent reflux back into the pharynx. The UES produces pressures around 30–200 mm Hg. Two waves of peristalsis move the food into the stomach through the LES, which also produces pressures between 20 and 60 mm Hg. Afferent nerve fibers transmit to the dorsal vagal complex activating efferent fibers that terminate either on the striated muscle of the esophagus or on the nerves of the enteric nervous system. Release of acetylcholine contracts the muscle while VIP and nitric oxide (NO) relax it. The LES responds to esophageal distention via myogenic and neurohormonal mechanisms.

Diseases of the esophagus are varied. Etiologies can be grouped into anatomical, mechanical, and neurologic, although many disease states involve overlap between two or all three. Anatomical etiologies include the presence of diverticula, hiatal hernia, and changes associated with chronic acid reflux. These anatomical abnormalities interrupt the normal pathway of food as it travels to the stomach which, in turn, changes many of the pressure zones of the esophagus. This can have dangerous sequelae as the luminal pressures may increase enough to overcome the resting pressures of the UES and LES allowing for reflux. Mechanical etiologies include achalasia, diffuse esophageal spasm, and hypertensive LES. There is also a neurologic component to these diseases but the result is the same—the esophagus is unable to relax properly for food travel. In achalasia the smooth muscles are unable to relax and move food down and the increased tone of the LES does not allow for complete relaxation. This results in dysphagia, regurgitation, and significant pain. In diffuse esophageal spasm the muscle contractions are uncoordinated and, as a result, food does not properly move downward. A hypertensive LES is defined as an LES with a mean pressure of 45 mm Hg or higher leading to dysphagia and chest pain. Neurologic disorders such as stroke, vagotomy, or hormone deficiencies will alter the nerve pathways such that the appropriate sensing and feedback are disrupted. A common result of neurologic disorders in the esophagus is dysphagia.

In evaluating esophageal function, it is important to select a study with an appropriate clinical correlation—is it a problem with motility or is it an anatomical abnormality? If it is a questionable motility problem, then an esophageal manometry study is best. A special catheter detects changes in pressure in the esophagus at various levels. First the pressure of the LES is recorded. The catheter is then pulled back into the esophagus and pressure measurements are made at different levels. Esophageal motor function between swallows is also evaluated. Finally the motor function of the UES is recorded and then the catheter is pulled out. Questionable anatomical problems are best studied using an upper GI series and ingested barium. These evaluate the act of swallowing and visualize the lining of the esophagus for anatomic abnormalities.

Before discussing the transit of food through the stomach and small intestine it is important to understand their actions during the fasting state. The migrating motor complex (MMC) occurs only during fasting, and is composed of waves of electrical activity in regular cycles originating in the stomach and terminating in the distal ileum.[3] Vagal stimulation releases motilin, which triggers an MMC leading to peristaltic waves. They occur every 45 to 180 minutes and are composed of four phases. Phase I is a period of quiescence. Phase II is composed of increased action potentials and low-amplitude smooth muscle contractility. Phase III is the most active as it is the time of peak electrical and mechanical activity producing bursts of regular, high-amplitude contractions. Phase IV demonstrates declining activity and will merge into the following MMC's phase I. The MMC is significant because it moves residual undigested food through the GI tract and also moves bacteria from the small intestine to the large intestine. Feeding interrupts it, and this is discussed next.

As described previously, the stomach is a J-shaped sac that serves as a reservoir for large volumes of food, mixes and breaks down food to form chyme, and slows emptying into the small intestine. Solids must be broken down into 1 to 2 mm particles before entering the duodenum, and they take approximately 3 to 4 hours to empty from the stomach. Liquids empty faster than solids. The motility of the stomach is controlled by intrinsic and extrinsic neural regulation. Parasympathetic stimulation to the vagus nerve increases the number and force of contractions whereas sympathetic stimulation inhibits these contractions via the splanchnic nerve. The intrinsic nervous system provides the coordination for motility. Neurohormonal control is also at play in that gastrin and motilin will increase the strength and frequency of contractions and the gastric inhibitory peptide will inhibit them.

Emptying of the stomach is controlled by neural and hormonal mechanisms as well as the composition of ingested food. Gastric distention, gastrin, and NO will promote emptying. Duodenal distention decreases the gastric tone to slow emptying, and increased fat content triggers the release of cholecystokinin to further inhibit stomach motility.

Gastric motility disorders that slow its emptying can increase the incidence of GE reflux disease. These disorders can be drug-induced, neurologic, or a result of critical illness. Drug-induced conditions include the administration of opioids (to be discussed later in the chapter), and the use of vasoactive agents. Vasoactive drugs increase catecholamine concentrations leading to sympathetic stimulation and, therefore, decreased motility. These drugs are often given intraoperatively or to critically ill patients for blood pressure control. Neurologic disorders resulting in decreased gastric motility include vagal neuropathies and gastroparesis. Finally, conditions that are commonly present in severely compromised patients, such as those with hyperglycemia, increased intracranial pressure, and mechanical ventilation can decrease gastric motility. Efforts to increase motility using drugs like erythromycin and metoclopramide have been used with some success.

The most prevailing test to evaluate gastric motility is the gastric emptying study. The patient fasts for at least 4 hours prior to the study then consumes a meal with a tightly bound radiotracer, commonly egg albumin. Continuous or frequent imaging occurs for the next 60 to 120 minutes and the measurement of time for 50% of the ingested meal to empty is determined. It is important to note that while gastric emptying scintigraphy has long been the standard study, it is affected by multiple factors including meal composition and data acquisition parameters.[4] Gastric motility studies can also be paired with small intestinal motility studies such as the small bowel manometry test. This will be discussed later.

Small intestinal motility mixes the contents of the stomach with digestive enzymes, further reducing particle size and increasing solubility. However, the major function of the small intestine is to circulate the contents and expose them to the mucosal wall in order to maximize absorption of water, nutrients, and vitamins before entering the large intestine. Again, there are mixing contractions and propulsive contractions. The circular and longitudinal muscle layers work in a coordinated fashion to achieve segmentation. Segmentation occurs when two nearby areas contract and thereby isolate a segment of intestine. Then a contraction occurs in the middle of that isolated segment, further dividing it. Contractions in the middle of those segments continue to occur and the process ensues. Segmentation allows the contents to remain in the intestine long enough for the essential substances to be absorbed into the circulation. It is controlled mainly by the enteric nervous system with modulation of motility by the extrinsic nervous system.

When considering small bowel dysmotility it is helpful to distinguish etiologies based on reversible and nonreversible causes. For reversible causes, mechanical obstruction should be the first to come to mind. In this case, there is a physical obstruction the muscles of the intestine cannot overcome. Hernias, malignancy, adhesions, and volvuluses are all examples. Bacterial overgrowth should be another consideration. Although the large intestine is rich with bacteria, the small intestine usually has fewer than 100,000 organisms per milliliter. Disrupting this condition with bacterial overgrowth leads to alterations in absorptive function leading to diarrhea. It is treated with antibiotics. Other reversible causes include ileus, electrolyte abnormalities, and critical illness. Nonreversible causes can be classified as structural or neuropathic. In structural causes there may be abnormalities with the intestinal smooth muscle, in which it cannot produce proper contractions. This occurs in diseases such as scleroderma and connective tissue disorders. In patients with an inflammatory bowel disease (IBD), there is a structural abnormality in the mucosa leading to decreased absorption of nutrients. Short bowel syndrome can be considered a structural etiology in that a large portion of the small intestinal structure is simply not present. In patients who have had a section of their small bowel resected, the remaining portion may not provide sufficient functional compensation, resulting in diarrhea, malnutrition, and weight loss. Neuropathic etiologies can produce a pseudo-obstruction in which the intrinsic and extrinsic nervous systems are altered in such a way that the intestines can only produce weak or uncoordinated contractions. This leads to symptoms of bloating, nausea, vomiting, and abdominal pain. Regardless of etiology, small intestinal dysmotility adversely affects nutrient absorption leading to malnutrition.

The most common test used to evaluate small intestine motility is small bowel manometry. This test is useful in patients with unexplained nausea, vomiting, abdominal pain, and manifested signs of obstruction without a clear obstructive cause. Similar to esophageal manometry, this test uses a small catheter with pressure sensors to evaluate the contractions of the intestine. The study evaluates contractions during three periods: fasting, during a meal, and postprandial. Normally the recording time is four hours for fasting, followed by ingestion of a meal, and two hours postprandial. Abnormal results are grouped into myopathic and neuropathic causes. In myopathic results, the MMC is absent or phase III exhibits very low amplitudes (normal phase III amplitude is 40 mm Hg). In neuropathic results, the contraction amplitude is adequate but either the contractions are uncoordinated (enteric neuropathy) or there is an inappropriate postprandial response, meaning postprandial antral hypomotility is present (extrinsic neuropathy). This manometry test is reported to result in a change of diagnosis in 8% to 15% of patients with unexplained nausea, vomiting, and abdominal pain.[5]

The large intestine acts as a reservoir for waste and indigestible material before elimination and extracts any remaining electrolytes and water. It plays an essential role in regulating defecation and consistency of stools. Distention of the ileum will relax the ileocecal valve to allow intestinal contents to enter the colon and subsequent cecal distention will contract it. The contractions of the colon are different from the rest of the gut. While there are still mixing and propulsive movements by the circular and longitudinal muscles, respectively, the colon also exhibits giant migrating complexes. The giant migrating complexes serve to produce mass movements across the large intestine. In the healthy state, these complexes occur approximately 6 to 10 times within 24 hours with mean amplitude of 115 mm Hg at a distance of about 1 cm/s for approximately 20 seconds each.[6] These complexes, as well as the mixing and propulsive movements, serve to transfer contents to the rectum. The giant migrating complexes that originate in the sigmoid colon will produce the urge to defecate. Rectal distention as well as VIP and NO release will promote relaxation of the internal anal sphincter and allow for defecation.

Colonic dysmotility manifests with two primary symptoms: altered bowel habits and intermittent abdominal cramping. The most common diseases associated with colonic dysmotility are irritable bowel syndrome (IBS) and IBD, both of which are clinical diagnoses. Rome II criteria define IBS as having abdominal pain/discomfort along with at least two of the following three features: defecation relieves pain or discomfort, onset of pain is associated with an abnormal frequency of stools (more than three times per day or fewer than three times per week), and onset of pain is associated with a change in the form of the stool.[7] In IBS with predominantly diarrheal symptoms, there is an increase in the frequency and amplitude of spontaneous giant migrating complexes, and this increase is directly proportional to the severity of symptoms. In IBS with predominantly constipation, there is a decreased amplitude and frequency of giant migrating complexes. In severe cases the giant migrating complexes may be completely absent. In addition, there is a depression of overall contractile activity in the colon leading to colonic distention and the sensation of pain. This phenomenon is exacerbated by stress in which there is significant motor dysfunction and visceral hypersensitivity as well as an increase in plasma norepinephrine stimulating the sympathetic nervous system. In IBD the mixing and propulsive movements as well as the tonic contractions are suppressed due to colonic wall compression by the inflamed mucosa, but the giant migrating complexes remain. There is an increased frequency of the giant migrating complexes and their large pressure effect further compresses the inflamed mucosa, which can lead to hemorrhage, thick mucus secretion, and significant erosions.

Methods of Evaluating Colonic Motility

Studies evaluating giant migrating complexes in patients with IBS and IBD are not routine but are performed only on patients with known diagnoses to help understand the physiology and mechanism causing them. There are, however, tests to evaluate the function and anatomy of the large intestine. The lower GI series, for example, involves the administration of a barium enema to a patient. The barium outlines the intestine and it is visible on radiograph. This allows for detection of colon and rectal anatomical abnormalities.

The Effects of General Anesthesia on Bowel Function

GI effects of the anesthetics are multifaceted and encompass a wide array of hemodynamic and physiological changes. This section is broken down into the various components that make up a general anesthetic and the GI effects of each of these components. Emphasis is placed on the effects of preoperative sedation, induction of anesthesia, hypnotic agents, volatile agents, paralysis, and reversal. Opioids will be discussed in another section. Please note that this discussion applies to the healthy state.

In the preoperative setting patients are often nervous and sympathetic stimulation is high. Inhibition of GI tract activity is directly proportional to the amount of norepinephrine secreted from sympathetic stimulation, so the higher the anxiety the higher the inhibition. Even though a good bedside manner and the use of behavioral approaches are beneficial, these may not be sufficient and patients are often given premedication with a benzodiazepine, usually midazolam, to alleviate anxiety. Midazolam acts by enhancing the effect of neurotransmitter, GABA, on GABA-A receptors. A study by Castedal and associates looked at the effect of midazolam on small bowel motility using antroduodenojejunal manometry.[8] The vast majority of the studied variables were not affected by the use of midazolam, but one significant change was noted—an increased duration of phase III of the MMC in the proximal and distal parts of the duodenum, which shortened the MMC by 27%. A clear explanation for this is not evident but there are a couple of considerations. One, the sedative effect of midazolam may be the reason for the change in MMC activity because MMC activity differs between awake and sleep states. Another consideration is that the resultant reduced anxiety decreases sympathetic stimulation allowing for less inhibition and higher activity. However, when applied clinically, there was no real difference seen in small intestinal motility patterns. Of the premedications, midazolam is widely used and considered well tolerated.

General anesthesia causes a loss of all protective reflexes. This is achieved with a variety of medications including opioids, hypnotics, and neuromuscular blocking agents. As mentioned, the effect of opioids will be discussed in a later section. Volatile anesthetics affect bowel function through various mechanisms including depression of spontaneous activity and changes in intestinal tissue oxygenation. Volatile anesthetics depress the spontaneous, electrical, contractile, and propulsive activity in the stomach, small intestine, and colon as demonstrated in many animal and human studies. The small intestine is the first part of the GI tract to recover, followed by the stomach in approximately 24 hours and then the colon 30 to 40 hours postoperatively. Between the various volatile anesthetics there are minor differences. One difference worth noting is that rapid increases in the concentration of desflurane induces greater sympathetic activation, as compared to other volatile agents, which coupled with sympathetic nervous system hyperactivity during surgical procedures can inhibit GI function and motility. In a study comparing desflurane and isoflurane, rapid increases in desflurane caused significantly greater effects on sympathetic and renin-angiotensin system activity as well as increases in blood pressure and heart rate as compared to isoflurane. However, this effect is short-lived as it is only seen with rapid increases in concentration and the surge in sympathetic stimulation tapers off quickly. This transient phenomenon is unlikely to have a lasting effect on bowel function.[9] The volatile anesthetics also affect splanchnic circulation and oxygenation in a dose-dependent manner, which is known to have an effect on bowel function. In horses receiving isoflurane for maintenance of anesthesia, microperfusion and intestinal tissue oxygenation decreased when isoflurane reached 2%.[10] In a human study by Muller and associates, the effects of desflurane and isoflurane on intestinal tissue oxygenation during colorectal surgery were evaluated. It was found that desflurane and isoflurane had comparable effects on intestinal tissue oxygenation. However, during periods of ischemia for resection and anastomosis, reactive hyperemia was better preserved in the patients given isoflurane.[11] This may have important implications in regaining coordinated and appropriate bowel function postoperatively and may determine maintenance with volatile versus total intravenous anesthesia. Whereas the volatile anesthetics depress spontaneous activity and affect blood flow, there is no clear-cut relationship between adverse GI effects and the use of volatile anesthetics. Also, when considering their use in clinical practice, there is very little difference between desflurane, isoflurane, and sevoflurane's effects on bowel function.

An alternative to maintenance with volatile anesthetics is total intravenous anesthesia. Propofol is the most common drug used for this purpose. When used intraoperatively, propofol-remifentanil anesthetic produced increased intestinal motility as compared to sevoflurane-remifentanil.[12] No adverse GI effects were reported, but it did cause a higher degree of surgeon dissatisfaction. A study by Jensen and colleagues looked at bowel recovery after open procedures and did not find a difference in overall recovery and bowel function when comparing isoflurane/nitrous oxide, propofol/air, and propofol/nitrous oxide.[13] Even in colorectal cancer patients there was no difference in inflammatory response among patients receiving either total intravenous anesthesia with propofol and remifentanil or inhalational anesthesia with sevoflurane and fentanyl.[14,15] There are few data on the effect of propofol on GI smooth muscle and many of the established studies show various and conflicting results when it comes to the recovery of bowel functions.

Nitrous oxide is 30 times more soluble than nitrogen in the blood and as such will diffuse into gas-containing cavities from the blood faster than the nitrogen already present in those cavities can diffuse out. This is especially important in the bowels as gut distention is correlated with the amount of gas already present in the bowel, the duration of nitrous oxide administration, and the concentration of nitrous oxide administered. Although it has been established that nitrous oxide causes bowel distention and it is prudent to avoid nitrous oxide in lengthy abdominal surgeries or when the bowel is already distended, the most recent ENIGMA trial did not relate the use of nitrous oxide to any significant adverse outcomes.[16]

Paralysis to achieve favorable surgical conditions is produced by administration of neuromuscular blocking agents. Neuromuscular blocking drugs only affect skeletal muscle so GI motility remains intact. However, special mention of the depolarizing neuromuscular blocker succinylcholine should be made. Succinylcholine mimics acetylcholine in that it produces an initial muscle contraction, which is visible as fasciculations. This contraction increases intragastric pressure, which may be so strong as to overcome the tone of the LES and allow reflux of gastric contents. Aspiration is certainly a concern, but this should not necessarily preclude the use of succinylcholine. Patient condition, including body habitus, technical difficulty of intubation, nothing by mouth (NPO) status, and comorbidities should be the determining factors in assessing the risk of aspiration.

Reversal of paralysis using the anticholinesterase, neostigmine, will increase parasympathetic activity and bowel peristalsis by increasing the frequency and intensity of contractions. In cases of fresh bowel anastomoses, this can be of concern as the increase in activity could result in dehiscence. This is partially offset by simultaneous administration of the anticholinergic medications, glycopyrrolate or atropine, which are used to attenuate the bradycardia from neostigmine. This effect is not seen with sugammadex, which may be a more prudent choice for reversal in situations of tenuous bowel anastomoses. There is some data to support the use of neostigmine in treating postoperative ileus but the adverse effects of bradycardia, vomiting, and abdominal cramps may preclude its use.

Surgical procedures on the GI tract produce an exaggerated stress response that may predispose to postoperative bowel dysfunction. Goals of anesthetic care should be to attenuate the stress response, optimize hemodynamic and fluid status, and maintain normothermia.[17,18] At present there is no evidence for recommendations on specific anesthetic and analgesic agents to avoid adverse GI effects.

Effect of Opioids on Bowel Function

Much attention has been given to the use and effects (beneficial and adverse) of opioid administration. There is a desire to only use adjunct techniques and nonopioid medications; however, opioids are often necessary to control perioperative pain. A major adverse effect, and one that is not associated with the development of opioid tolerance, is reduced GI motility and constipation. Opioids exert their function on both central and peripheral receptors, namely mu, delta, and kappa. It is the central effects that primarily mediate analgesia and produce the favorable effects. The peripheral effects are the adverse effects. There is a high density of peripheral mu-opioid receptors in the myenteric and submucosal plexuses. Activation of these mu-opioid receptors in the myenteric plexus has a dual effect on the neural pathways controlling motility—it inhibits excitatory pathways that depress peristaltic contraction and it also inhibits inhibitory pathways. These inhibitions increase GI muscular activity and increase resting muscle tone including tone in the ileocecal valve and internal anal sphincters. This produces spasm and nonrhythmic or propulsive motility. Activation of these receptors is also linked to the inhibition of acetylcholine release and promotion of nitrous oxide release that inhibits propulsive motility.[19] Together these effects will delay gastric emptying and slow transit through the intestine. Activation of these receptors in the submucosal plexus decreases nutrient secretion and increases fluid absorption. Coupled with reduced motility the stool will remain in the gut for a longer period of time and as more water is absorbed the stool becomes hard and dry leading to constipation.[20] Other adverse sequelae include nausea, anorexia, delayed digestion, abdominal pain, excessive straining during bowel movements, and incomplete evacuation.

Many efforts have been made and are currently underway to attenuate or avoid opioid-induced bowel dysfunction. The use of laxatives, stool softeners, and prokinetic agents, such as metoclopramide and neostigmine, have shown some success in alleviating opioid-induced constipation. Potentially switching to a different opioid is also offered as a treatment option. Tassinari and associates performed a meta-analysis demonstrating strong evidence supporting opioid switch in alleviating constipation, most strongly for morphine to transdermal fentanyl.[21] Another option is combining opioids with enteral opioid receptor antagonists. Naloxone was the first used. It is a nonselective, competitive opioid receptor antagonist. While its effect on the peripheral receptors in the gut produced favorable results of reversing gut motility inhibition, its nonselective profile meant it also worked on the central receptors and reversed the beneficial analgesic effect of opioids. Therefore, new attention is given to pure peripherally acting opioid receptor antagonists. Methylnaltrexone is a peripheral mu-opioid receptor antagonist and does not cross the blood-brain barrier. In healthy volunteers, the use of methylnaltrexone prevented delay in orocecal transit time after morphine administration.[22] Subsequent systematic reviews demonstrated that methylnaltrexone and alvimopan were better than placebo in reversing opioid-induced increased GI transit time and constipation.[23–25] However, long-term efficacy and safety have not been clearly established. Further studies are underway.

Effect of Open Abdominal Surgery, Ischemia, Stomas, and Bowel Anastomosis on Gastrointestinal Physiology and Function

The surgical procedure itself, even with purposes of correcting GI pathology, significantly affects GI physiology and function and predisposes to postoperative ileus. Recently, a standardized definition of postoperative ileus was established as "a transient cessation of coordinated bowel motility after surgical intervention, which prevents effective transit of intestinal contents and/or tolerance of oral intake."[26] Manipulation of the intestines is the main factor that initiates postoperative ileus. Additional contributors include immobility, electrolyte imbalance from fluid shifts and insensible losses, and intestinal wall swelling from excessive fluid administration. In open abdominal procedures, the surgical manipulation of the bowel induces a degree of trauma that sets in motion the whole process of postoperative ileus. There are two phases to uncomplicated postoperative ileus (i.e., in the absence of complications, such as perforation, bleeding, peritonitis). The first phase is an early neurogenic phase and the second is an inflammatory phase. In total, an uncomplicated postoperative ileus lasts about 3 to 4 days.[26]

The early neurogenic phase results when the intestine is manipulated, which is more extensive in open procedures than laparoscopic ones. This manipulation activates the sympathetic nervous system, increasing the inhibitory neural input that leads to decreased propulsive movements and almost complete cessation of GI motility. This lasts about 3 to 4 hours after surgery.

The late inflammatory phase also begins with surgical manipulation of the intestines. Surgical manipulation increases sympathetic stimulation of the myenteric plexus, which promotes the influx of leukocytes into the "traumatized" areas of the gut. Further release of cytokines, chemokines, and leukocytes as well as phagocytosis in the traumatized area occurs and eventually spreads through the entire GI tract. This inflammatory cascade increases permeability and allows for translocation of intraluminal bacteria, which further exacerbates the inflammatory process. However, peritonitis does not always develop because the mast cells and neutrophils are very effective in eliminating the translocated bacteria in the peritoneal cavity. This process occurs about 3 hours after intestinal manipulation and continues throughout the manipulated segment and the rest of the GI tract for the next 24 hours. It eventually subsides and within 3 to 4 days this uncomplicated ileus is usually resolved.[27,28]

Mesenteric ischemia, if left untreated, will lead to 100% mortality. This occurs when the supply of oxygen is insufficient to meet the oxygen demand of the intestines. It affects the small and large intestine and is classified as occlusive or nonocclusive. Etiologies of mesenteric ischemia include: strangulation, emboli (seen commonly in patients with atrial fibrillation), complications of aortic surgery or during cross-clamping, trauma, drug-induced, atherosclerosis, and inflammatory diseases. There are four stages of mesenteric ischemia. The first is the hyperactive stage when blood flow to the intestine is abruptly occluded. This produces severe pain and overactive peristalsis. There may be passage of loose stool with blood. The second stage is a paralytic stage that spreads diffusely across the intestines. The third stage involves leakage of fluid, proteins, and electrolytes through the bowel wall into the peritoneum. If the bowel becomes necrotic then peritonitis develops. The fourth stage is shock. End-organ damage is apparent and contributes to altered hemodynamics and critical illness. Treatment involves reperfusion of the occluded vessel through revascularization and possibly bowel resection.[29]

Bowel resections vary in terms of their effect on the remaining bowel. The degree of GI dysfunction depends on the portion of bowel resected. The colon primarily absorbs water and a full colonic resection is compatible with life. However, when the small intestine is resected the effect on the GI system is much more pronounced. The small intestine is responsible for absorbing vitamins and nutrients. This can be properly maintained if at least a third of the small bowel remains. The jejunum is the primary site for digestion and absorption of nutrients. After a jejunal resection, the ileum is usually able to adapt to fulfill its functions. The ileum absorbs vitamin B12 and bile salts. If the ileum is resected (especially more than 100 cm), the remaining small intestine cannot compensate for the loss of its function and severe malabsorption and diarrhea will result. The unabsorbed bile salts enter the colon and stimulate fat and water secretion. Small intestinal resection will increase gastric motility but this depends on the site and amount resected. If the terminal ileum and ileocecal valve are resected then intestinal content transit speeds up.[30]

Bowel anastomoses can significantly alter bowel function in that they disrupt normal motor activity. Partial transection usually preserves the wave of activity, though complete transection will interrupt it. There is a loss in myogenic continuity in that the intestine distal to the transection will no longer receive signals or respond to the pacemaker in the proximal duodenum. Now the part distal to transection has to rely on its own intrinsic slow-wave transmission. This can be attenuated by close approximation of the muscle layers. There is motor asynchrony across the anastomotic site but long-term studies report reasonable MMC activity is ultimately achieved with time. The mechanism explaining why this recovery occurs remains uncertain. The transection and anastomosis have little effect on intestinal homeostasis and are not associated with significant digestion or absorption side effects.[2]

Gastrointestinal System Nociception

Abdominal visceral pain and its associated symptoms are common in the GI perioperative period. For an understanding of GI nociception, a detailed knowledge of the anatomy and physiology of abdominal visceral innervation is essential.

ABDOMINAL VISCERA INNERVATION

Abdominal visceral pain signals are carried in both sympathetic and parasympathetic autonomic fibers.[31,32] Innervation of the parietal peritoneum, abdominal wall muscles, and skin is supplied by the ventral rami of thoracoabdominal nerves, which are part of the somatosensory system.

Sympathetic fibers for the upper abdomen, including the liver, stomach, pancreas, small bowel, and proximal part of the colon, originate from spinal cord segments T5 to L2. Those preganglionic fibers exit the cord as gray rami communicants to enter the sympathetic chain in the paravertebral region. These fibers terminate in the prevertebral (subdiaphragmatic) ganglia through splanchnic nerves and generate the celiac plexus, where they synapse with a large number of postganglionic, predominantly unmyelinated fibers. Postganglionic fibers will then innervate the

Sympathetic innervation of majority of the GI tract up to the rectum is supplied by the celiac plexus. (From Glick DB. The autonomic nervous system. In: Miller RD, ed. *Miller's Anesthesia*. 7th ed. Philadelphia: Elsevier; 2010.)

organs (see Fig. 15.5).[33] Innervation of the lower abdomen including the descending colon, sigmoid and rectum, bladder, and lower ureter originates from T9 to L3 and forms the inferior mesenteric and hypogastric ganglia and plexus.

Sympathetic afferent fibers transmit visceral pain, whereas sympathetic efferent nerves inhibit peristalsis and gastric distention as well as cause GI vasoconstriction.[33]

The parasympathetic nervous system supplies the abdominal viscera proximal to the splenic flexure of the colon via the vagus nerve. Some of the vagal fibers pass through the prevertebral fibers (celiac plexus). The parasympathetic postganglionic neurons are located in the myenteric and submucosal plexuses. Visceral afferent parasympathetic nerve fibers transmit the sensations of satiety, nausea, and distention, whereas efferent parasympathetic nerve fibers increase functions such as secretion, sphincter relaxation, and peristalsis.[34–36]

The colon, rectum, internal and external genitalia, and bladder are innervated by fibers from spinal cord segments S2 to S4, which run with the pelvic nerves (Fig. 15.1).[37–40]

Some of the characteristics of abdominal visceral innervation are: (1) they are almost exclusively myelinated A-delta and unmyelinated C fibers; (2) they have “dual-function” properties (sensory that carry sensory evoked potentials and afferent that regulate autonomic flow);[42]

(3) there are an abundance of connections between nerves, ganglia, and plexuses; (4) there is not a fine and distinct nerve; (5) considerable variation in anatomy can be found; (6) visceral innervation anatomy is affected by intraabdominal pathology; and (7) visceral innervation distribution is diffuse and capable of amplification. Once stimulated, it could be difficult to stop (self-aggravation).[41–46]

In summary, the innervation of the GI organs up to the proximal transverse colon is supplied by the celiac plexus, and innervation of the descending colon and distal GI tract comes from the inferior hypogastric plexus. Although each organ looks like it is innervated from specific cord segments, the fibers frequently communicate with each other (Table 15.2).

CELIAC PLEXUS ANATOMY

The celiac plexus is normally composed of two or three splanchnic nerves:

The greater (superior thoracic) splanchnic nerve comes from T5 to T9 (fibers can arise as high as T1 and as low as T11). The greater splanchnic nerve is usually anterolateral to the T12 vertebral body. It perforates the crura of the diaphragm and enters the retroperitoneal space where it joins the celiac plexus.

The lesser splanchnic nerve is formed from T9 to T11. In 30% of cases this nerve is not present. Two or more celiac ganglia are generated, which lie ventrolaterally to the aorta between the origin of the celiac arterial trunk and the renal arteries.

The celiac ganglia can vary considerably in size and number on each side. Usually they are oval shaped and can vary from 0.5 to 4.5 cm in width.

Fusion of these ganglia form a fine nerve plexus that may extend to the inferior border of the T12 vertebra and lower border of L2. They are mostly located close to the celiac artery trunk.[46]

The plexus and related nervous structures are contained in the prevertebral retroperitoneal space along with the aorta, inferior vena cava (IVC), veins of azygos system, lymph nodes, the cisterna chyli, and diaphragmatic crura (Fig. 15.2).

ABDOMINAL VISCERAL PAIN

Despite the fact that abdominal pain of visceral origin is a very common finding during the perioperative period, our knowledge and practice to control this pain are very limited.[47]

Visceral pain is different from somatic pain in many aspects; not all organs respond similarly to stimuli, some organs are more sensitive. For example, the pancreas is more sensitive than the stomach. Tissue destruction, ischemia, and inflammation will not always cause pain.[48] The most remarkable difference between visceral and superficial structures is the fact that visceral pain is poorly localized, produces strong affective responses, and refers to other locations with intense regional or muscle spasms and autonomic instability.[49–51]

The referral properties of visceral pain have been attributed to the conjunction of visceral and somatic inputs to the spinal cord and CNS. For the same reason, visceral pain can have somatic components. Merging of these inputs can modify pain sensation distal to the site of visceral inflammation, or pain from one intraabdominal organ can refer to another.[40]

Visceral pain is fervently associated with emotional fluctuation. IBS is thought to be related to gut-brain interaction and autonomic dysregulation.[52]

It was found that induced sadness was attenuated by fatty acid infusion, and increased neural activity in the part of the brain processing emotions was also observed.[53] Probiotic bacteria are beneficial in stress-related disorders, such as anxiety and depression, and during the course of common comorbidities and some bowel disorders.[54]

VISCERAL PAIN TREATMENT

Opioids are still the mainstay of visceral pain treatment, although their usage has been limited by many side effects such as decreased gut motility and constipation, sedation, nausea, and vomiting. In addition, prolonged usage of narcotics is associated with opioid-induced hyperalgesia and tolerance.[55] Usage of acetaminophen, nonsteroidal anti-inflammatory drugs, and serotonin components have been suggested, but the results are not specific.[56]

VISCERAL PAIN BLOCK TECHNIQUES

Noxious pain impulses originating from abdominal viscera can be blocked by the following regional anesthesia techniques (Fig. 15.3)

1. Spinal anesthesia extending to at least the level of T5
2. Epidural anesthesia covering T5 to Tl2 dermatomes
3. Paravertebral blocks comprising T5 to L2 spinal segments
4. Selective T5 to L2 sympathetic chain block
5. Celiac/splanchnic nerve block

Fig. 15.3 **Regional anesthetic techniques on gastrointestinal (GI) visceral sympathetic innervation: different regional techniques which can block sympathetic innervation of the GI tract at different levels.** (From Glick DB. The autonomic nervous system. In: Miller RD, ed. *Miller's Anesthesia*. 7th ed. Philadelphia: Elsevier; 2010.)

Based on the type and extent of the regional technique, its effect on the GI physiology is different. Of note, the aforementioned regional anesthesia techniques are associated with the blockade of the sympathetic nervous system, whereas the parasympathetic system usually remains intact.

VISCERAL/CELIAC PLEXUS BLOCK

Blockage of the splanchnic/celiac plexus has been approached in many ways:

Intraperitoneal Regional Anesthesia or Peritoneal Lavage

Abdominal visceral pain can be blocked simply by instilling local anesthetic into the peritoneal cavity. A recent meta-analysis by Boddy and associates of intraperitoneal regional anesthesia in laparoscopic surgeries found an overall benefit, although there was no consistent analgesia, but also a remarkable absence of complications and side effects.[57]

Celiac Plexus Block—Posterior and Trans-Crural Approach

Radiography, fluoroscopy, or computed tomography scan is usually needed to perform this block safely, especially in lytic blocks.

This approach requires a special needle, usually a 15-cm, 20- or 22-G Chiba needle. The patient is in the prone or lateral position and the needle is inserted below the tip of the 12th rib on the left side. The needle is aimed at a 45-degree angle to touch the lateral side of the L1 vertebral body at a depth of 7 to 9 cm. Subsequently, the needle is nearly fully redirected 5 to 10 degrees and advanced to a depth of 11 to 14 cm. In this situation the pulsation of the aorta on the needle can sometimes be felt (Fig. 15.4).

Determination of the correct vertebral level is imprecise in patients with absence of the 12th rib, a markedly downsloping of the rib, or in other congenital abnormalities.

Celiac Plexus Block—Anterior Approach

The abdomen is opened and the left lobe of the liver is retracted upward. The stomach is pulled gently downward and to the left thereby exposing and stretching the lesser omentum. The index finger of the operator is then inserted at the highest possible point of the incision, palpating the pulsating aorta through the lesser omentum. The aorta is pushed aside to the left by passing the tip of the finger to the vertebrae whereby it is separated from the vena cava. A fine 22-G spinal needle is inserted alongside the finger and in the loose, retroperitoneal, prevertebral tissue between the IVC and aorta. Diluted local anesthetic is injected in this area after careful aspiration. The tip of the needle should be close to the diaphragm, above the origin of the celiac trunk, in the midline. A similar approach was described by Lillemoe in 1992 for postoperative pain control in pancreatic cancer patients: after lesser omentum exposure, the left index and middle fingers are placed on either side of the aorta and pulled caudad until the upper border of the pancreas is identified and 20 mL of solution is injected on either side of the aorta (Fig. 15.5).[58]

Endoscopic Ultrasound-Guided Celiac Plexus Block

Recent recognition that the celiac ganglia can be visualized and accessed by endoscopic ultrasound (EUS) now allows for a direct injection into the celiac plexus. The patient is placed in the left lateral decubitus position and under conscious sedation. From the posterior side of the lesser curvature of the gastric fundus EUS can visualize the aorta in a longitudinal plane. The aorta is traced distally to the celiac trunk, and the injection delivered around the celiac trunk. Meta-analysis has shown that EUS-guided celiac plexus blocks are safe and efficient (Fig. 15.6).[59]

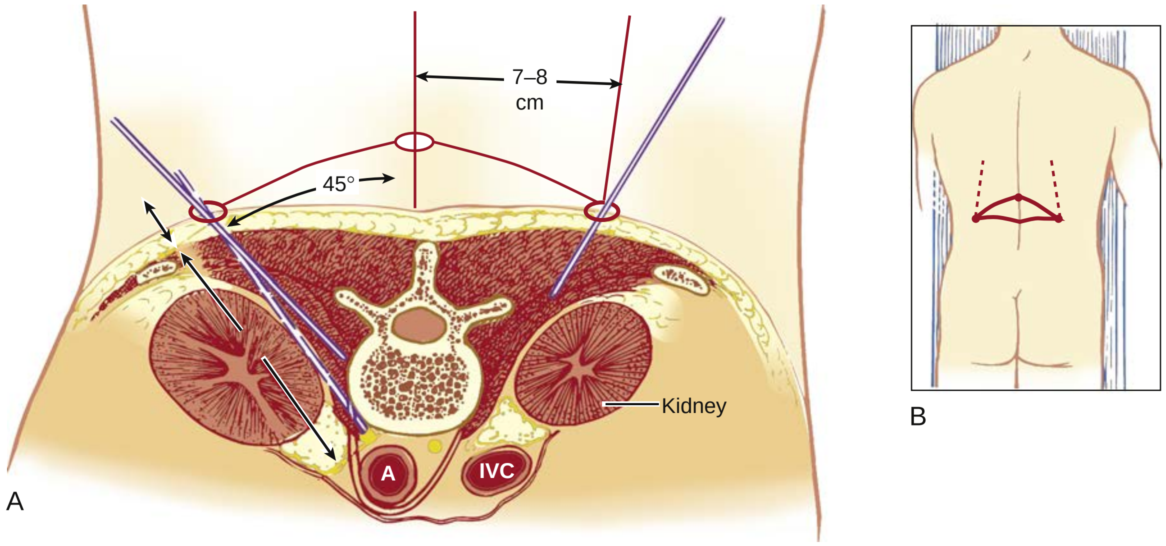

Fig. 15.4 (A) Schematic view of the posterior approach. Celiac plexus can be blocked by insertion of a 20- to 22-gauge 15-cm spinal needle (Chiba needle) at the level of T12. (B) Positioning and surface landmarks. (From Wedel DJ, Horlocker TT. Nerve blocks. In: Miller RD, ed. *Miller's Anesthesia.* 7th ed. Philadelphia: Elsevier; 2010.)

TECHNICAL ASPECTS OF VISCERAL PLEXUS BLOCKS

There is no established standard technique. It is important to completely disrupt all of the impulse traffic in the visceral innervation, as these impulses are widely spread and can be reinstated via very fine nerves.

Unfortunately, the success of splanchnic nerve and celiac plexus blocks cannot be verified by any objective signs. Hypotension is not a regular finding. If patients do have upper abdominal pain, analgesia typically results within a few minutes after the block. Failure of pain to subside is not only due to inappropriate technique but also due to the involvement of visceral plexuses, such as the hypogastric plexus.

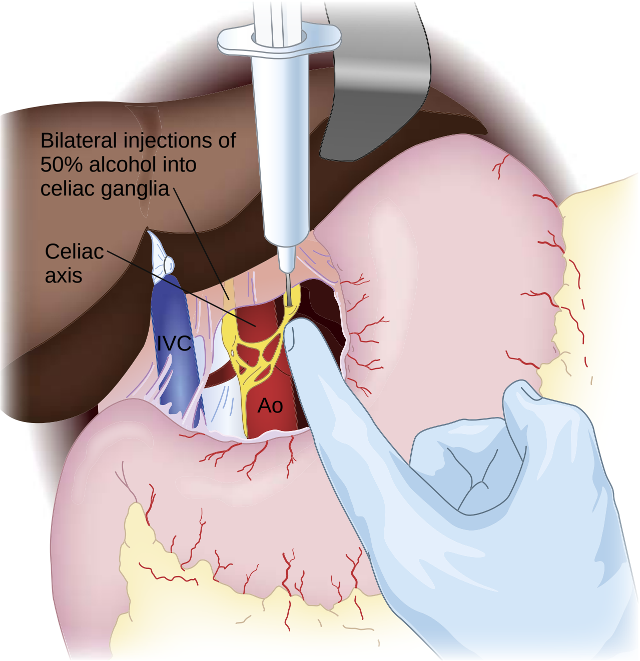

Fig. 15.5 Celiac plexus block (anterior approach): intraoperative celiac plexus block is performed using a 20- to 22-gauge spinal needle. Injection is performed at each side of the aorta and the level of celiac axis. (Redrawn from Lillemoe KD, Cameron JL, Kaufman HS, et al. Chemical splancnicectomy in patients with unresectable pancreatic cancer. A prospective randomized trial. *Ann Surg*. 1993;217:447–457.)

BOX 15.1 Complications of Celiac Plexus Blocks

Hypotension
Diarrhea
Intravascular injection and vascular trauma
Subarachnoid or epidural injection and paraplegia
Renal injury
Pneumothorax
Chylothorax
Damage to surrounding structures and retroperitoneal hematoma
Peritonitis and abscess

There is little information about the duration of a successful block induced by local anesthetics. Most of the blocks have been a combination of local anesthetic and lytic therapy for chronic pain. In order to avoid toxic side effects, local anesthetic doses must be reduced when the block is combined with another major regional anesthetic technique such as abdominal wall blocks.

COMPLICATIONS OF VISCERAL PAIN BLOCKS

The complication rate is between 0.5% and 32%, depending on the method, as radiologic methods are associated with a reduced rate of complications (Box 15.1).

Dilation of the capacitance vessels in the splanchnic area will cause hypotension. Subarachnoid injection happens mostly with a posterior approach, and an alcohol injection can cause paraplegia.

A chylothorax can result from damage of the retroperitoneal lymph nodes.

The most devastating complication occurs with vascular trauma, thrombosis, and retroperitoneal hematoma.[60]

INDICATIONS FOR A VISCERAL PAIN BLOCK

Post-Laparatomy Pain Relief

Visceral pain blocks are usually associated with somatosensory pain controls using central neuroaxial regional anesthesia techniques, such as epidural analgesia or paravertebral analgesia. A combination of a celiac plexus block with any other regional anesthesia technique is rarely used.

Cancer Pain

Splanchnic/celiac plexus blocks have been used for biliary and pancreatic cancers. The details of this indication of visceral pain control are discussed in the chronic pain management chapter (Chapter 51).

EFFECTS OF REGIONAL ANESTHESIA ON GASTROINTESTINAL PHYSIOLOGY

The degree to which the GI tract is affected by regional anesthesia depends on the type and extent of the block. Epidural analgesia, especially thoracic epidural analgesia (TEA), has been used extensively for a wide variety of GI surgeries. The clinical outcome of TEA after GI surgeries has been reviewed extensively in the literature; the focus of this chapter is its effect on GI physiology.

Effect on Gastrointestinal Motility and Postoperative Ileus

As described, postoperative ileus is a very common phenomenon in patients who undergo major abdominal surgery. Postoperative ileus is a temporary state of GI motor dysfunction that occurs after surgery in the abdominal cavity. This includes disruption of normal coordinated movements of the GI tract,[61] nonmechanical obstruction of the bowel, activation of the inhibitory reflexes, inflammatory mediators, bowel manipulation, electrolyte disturbances, opioid administration, sympathetic overactivity with surgical pain, and postoperative pain.[62–66] Transit time of the stomach may extend 24 to 48 hours and colon transfer time may increase 48 to 72 hours. Some of these effects may continue for up to 3 to 4 days after surgery.[67,68]

The main pathophysiologic event in postoperative ileus is neuroimmune interaction, which is based on the bidirectional communication between the immune system within and outside the GI tract and the autonomic nervous system.[69]

Manipulation of the intestines and the stress response associated with postoperative pain are the key factors initiating postoperative ileus. The surgical stress response is a multifaceted, neurohumoral response to a surgical stimulation and can be associated with considerable morbidity, including a systemic inflammatory response syndrome, which is associated with the release of systemic inflammatory response and adrenaline and noradrenaline hormones. This sympathetic overactivity will constrain mobility and directly inhibit gut smooth muscle via activation of α- and β-adrenergic receptors resulting in postoperative ileus.[70] Epidural administration of local anesthetic or opioids has been shown to suppress these responses.[71–73]

Epidural block with deposition of local anesthetic within the epidural space results in blockade of the afferent and efferent sympathetic-mediated GI reflexes, but parasympathetic innervation is left intact. The effect of an imbalanced sympathetic and parasympathetic nervous system has been associated with improved GI blood flow and anastomotic mucosal perfusion. This controls pain and decreases the need for opioids.[74–78]

However, it should be noted that severe hypotension (>50% reduction in systolic blood pressure) may be associated with worsened local perfusion.[79,80] Vasoactive drugs, such as norepinephrine, can attenuate this effect and improve colonic perfusion.[81]

In general, epidural analgesia can effectively decrease the incidence of postoperative ileus. A Cochrane review showed that epidural usage reduces postoperative ileus by 36 hours when a local anesthetic regimen was used as compared to an opioid-based regimen.[82]

Effect on Enteric Anastomosis Dehiscence

Unopposed parasympathetic activity with blockage of sympathetic fibers has increased concerns among clinicians that the increased mobility and intraluminal pressures will lead to anastomotic leaks and possibly rupture.[83] However, animal studies have failed to show any difference in anastomotic bursting pressure when epidural anesthesia is compared to general anesthesia.[84] In fact, it could be argued that with improvement of GI blood flow and tissue oxygenation the neuroaxial block can actually reduce the risk of anastomotic breakdown. However, the effect of neuroaxial blocks after GI procedures and laparotomies on enteric anastomotic leakage is not supported in the literature.[81,85]

Effect on Nutrition

The early postoperative period after GI surgery is characterized by a systemic stress response and catabolic activity. This effect, in conjunction with a lack of nutrition, results in postoperative weakness and muscle wasting. As discussed previously, epidural analgesia has been shown to decrease opioid requirements and reduce postoperative ileus. This, in turn, enhances enteral feeding.[86] Therefore, blockade of afferent stimuli and the endocrine metabolic responses, as well as the improvement in catabolism seen with epidural analgesia, are part of an enhanced recovery after surgery (ERAS) protocol for major GI surgeries to facilitate oral nutrition.[87]

Effect on Postoperative Nausea and Vomiting

Pain management plays a large role in postoperative nausea and vomiting therapy.[88] Avoiding systemic opioids and the use of epidural analgesia helps to reduce the incidence of nausea and vomiting. However, in the setting of regional anesthesia, attention should be paid to unopposed vagal activity, local anesthetic systemic toxicity, hypotension, and medication administration.

Spinal anesthesia poses the highest risk for the development of nausea and vomiting and is seen in 20% of patients. The effects of spinal anesthesia, especially with T6 to L1 blockade, include sympathetic innervation and unopposed vagal activity and result in GI hyperperistalsis, nausea, and vomiting.[89] In addition, TEA or spinal anesthesia that results in systemic hypotension severe enough to cause cerebral ischemia can cause nausea and vomiting.[90]

Effect on Gastrointestinal Blood Flow and Volume

The degree of arterial hypotension induced by spinal or epidural anesthesia is directly related to the extent of the blockade, the dose of local anesthetic used, and baseline hemodynamics.[91] Lumbar epidural anesthesia leads to arterial and venous dilation at the segments affected by the anesthetic. The constriction of the proximal part of the splanchnic vasculature shifts blood volume from the splanchnic system into the systemic circulation and usually results in preservation of stressed volume and blood pressure. TEA is associated with pronounced mesenteric vasodilation and arterial hypotension, while intestinal blood flow and oxygen consumption are maintained**.** A study using labeled red cells demonstrated that epidural anesthesia with sensory block at T4 to T5 increased blood volume in both the intrathoracic and splanchnic vasculature. The addition of a vasoconstrictor decreased volume within the splanchnic region, but increased volume within the thorax. The authors estimated that the use of a vasoconstrictor during TEA led to a shift of approximately 1 L of blood from the splanchnic area into the thoracic and systemic circulation.[92] Infusion of fluid or the use of adrenergic agonists apparently increases stressed volume. Infusion of fluid increases total (stressed and unstressed) blood volume, whereas adrenergic agonists move existing blood volume from unstressed to stressed.[93] In many situations, the use of α-adrenergic agonists might be more beneficial than infusion of fluid. Because veins are much more sensitive to adrenergic stimulation than arteries are, small doses of α-adrenergic agonists in normovolemic patients would constrict veins (increasing stressed volume) without affecting arteries or jeopardizing tissue perfusion.

ENHANCED RECOVERY AFTER SURGERY FOR GASTROINTESTINAL PROCEDURES—PHYSIOLOGIC BASIS

ERAS is an interdisciplinary, multimodal concept aimed at accelerating postoperative convalescence and reducing general morbidity by simultaneously applying several interventions. ERAS represents a paradigm shift in perioperative care. It reexamines traditional practice by replacing it with evidence-based practices.[94]

ERAS for GI procedures highlights a perioperative regimen with emphasis on[95,96]:

1. Regional anesthesia
2. Avoidance of opioids
3. Multimodal analgesia
4. Nutrition and preoperative carbohydrates
5. Selective bowel preparation
6. Fluid optimization
7. Temperature control
8. Early removal of drains and tubes
9. Early mobilization
10. Early oral intake

The use of ERAS protocols has been associated with shorter hospitalizations.[97]

PHYSIOLOGIC BASIS OF ERAS

Perioperative Pain Control

Many aspects of regional anesthesia, opioid-sparing anesthesia, and multimodal analgesia have already been discussed. The effect of pain control on postoperative outcomes has also been evaluated in multiple studies and is an inseparable part of ERAS protocols for many surgeries including GI procedures.[98–100] The favorable physiologic effects on the respiratory and cardiovascular systems by epidural analgesia may serve as yet another reason as to why epidural analgesia is a devoted part of ERAS protocols.[101–102]

Preoperative Carbohydrate Loading and Early Postoperative Feeding

There is strong evidence in animal studies demonstrating that fed animals tolerate stress much better than fasted animals. Perioperative oral carbohydrates raise insulin sensitivity by 50%. This means there is 50% less insulin resistance in the postoperative period, which also ameliorates ilium barrier failure. There is also less risk of development of hyperglycemic events and an improvement in retention of protein and lean body mass.[103,105] Enteric feeding is associated with prevention of bacterial translocation[104] or gut barrier failure.[105] Carbohydrate loading shifts the cellular metabolism to an anabolic state that will support postoperative nutrition.[106–108]

Most of the national and international societies now recommend a 6-hour preoperative fast for solids and a

2-hour fast for clear fluids, which includes carbohydrate drinks.[109–112]

In order to maintain metabolic and nutritional homoeostasis, early postoperative feeding has been suggested. A small study on patients after major colorectal surgery showed that immediate postoperative enteral feeding does not result in a net loss of body nitrogen.[113]

Temperature Control

In addition to the adverse effects of hypothermia (<35°C) on coagulation, cardiac, respiratory, and neurologic function, hypothermia triggers a whole-body thermoregulatory vasoconstriction response. Consequently, it reduces cutaneous flow and can result in tissue hypoxia and failure of the humoral immune defense system.[114–116] Hypothermia is associated with a threefold increase in the incidence of surgical site infection.[117]

Nasogastric Tubes

Regular use of nasogastric tubes following major intraabdominal surgery is for gastric decompression, thereby preventing anastomotic leakage and promoting early return of bowel function. However, routine use has been questioned as it is very uncomfortable for the patient and there is an associated risk of developing pulmonary complications, delays in the return of bowel function, and increasing the rate of wound infections.[118] In addition, the presence of gastric tubes is associated with increased gastric secretion and motility—a physiologic response to the presence of a foreign body.

Bowel Preparation

Bowel preparation for major GI procedures has been implemented in order to reduce postoperative complications related to infected bowel content,[119] with polyethylene glycol a most popular preparation. Adverse physiologic effects of this bowel preparation include decreased exercise capacity, lower weight, increased plasma osmolality, decreased urea and phosphate, and reduced plasma calcium and potassium.[120] These effects along with fasting can produce a very unpleasant experience for the patient.

The routine use of bowel preparation has been questioned repeatedly. In fact, recent studies have shown that mechanical bowel preparation can be safely omitted before elective colorectal surgery.[121,122]

Drains

Intraabdominal drains are placed to prevent accumulations of intraabdominal collections, to quickly discover postoperative bleeding, to diagnose anastomotic leakage, and to drain intraabdominal abscesses. However, routine use of drains simply placed prophylactically after major abdominal surgeries has recently been questioned. These drains are not innocuous as they can be associated with bacterial contamination, wound infection, incisional hernia, intestinal obstruction and fistula formation, and bleeding.[123] There is insufficient evidence to support the notion that routine use of drainage after colorectal anastomoses can prevent anastomotic leakage or any other related complications.[124]

Fluid Management

All patients having elective surgery undergo a preoperative starvation period that results in a fluid deficit. Typically, it is not enough to produce major fluid shifts, but it may stimulate the production of antidiuretic hormone, atrial natriuretic peptide, the renin-angiotensin-aldosterone system, and an increase in sympathetic activity. This relative hypovolemia is also more pronounced in patients who receive bowel preparation, experience diarrhea or vomiting, are exposed to high temperatures, or have high nasogastric tube output.

Recent NPO guidelines allow patients to have clear fluids up to 2 hours prior to surgery.[125] Intraoperative fluid management takes into account the preoperative fluid deficit, the presence of a regional anesthesia technique, hemorrhage, and third-space losses. However, prudent administration of intravenous fluids is necessary as free and rapid administration of salt and water will increase capillary hydrostatic pressure, cause tissue and bowel edema, and adversely affect anastomotic integrity. Optimizing fluid administration should focus on increasing tissue perfusion and oxygen delivery, and modulation of the hormonal and inflammatory response.[126]

Mobilization and Early Ambulation

Early postoperative ambulation is recommended for prevention and treatment of postoperative ileus.[127,128] It is believed that early ambulation helps with the restoration of normal bowel function. However, studies demonstrate that GI myoelectrical activity patterns are not always expedited by early postoperative ambulation; at least there is no correlation with the extent of ambulation.[129] Yet, early ambulation confers many other advantages, specifically prevention of postoperative thromboembolism and pulmonary complications.[130,131]

Acknowledgment

The editors and publisher would like to thank Drs. Matthias F. Stopfkuchen-Evans and Simon Gelman for contributing a chapter on this topic in the prior edition of this work. It has served as the foundation for the current chapter.

Hepatic Physiology, Pathophysiology, and Anesthetic Considerations

DOLORES B. NJOKU, HOVIG V. CHITILIAN, and KATE KRONISH

KEY POINTS

- The liver is the largest abdominal organ and carries out a number of vital functions including metabolism and detoxification.
- The liver receives approximately 25% of the resting cardiac output. The hepatic artery is responsible for 25% to 30% of the blood supply to the liver while the portal vein is responsible for 70% to 75%. They each deliver 50% of the total oxygen to the liver.
- For the purpose of hepatic resection, the liver can be divided into eight segments based on independent blood supply and drainage of blood and bile. A segment can be resected without compromising the blood flow and biliary drainage of other segments.
- The acinus is the basic functional unit of the liver. It is organized around the flow of blood from the portal triad to the central vein through the sinusoids. Hepatocytes in the acinus are organized into zones based on their proximity to the portal triad or central vein. Zone 1 or periportal hepatocytes are closer to the portal triads and receive oxygen and nutrient-rich blood. Zone 3 or perivenous hepatocytes are closer to the central veins and receive oxygen-poor blood. Hepatocytes in different zones serve different anatomic functions.
- The liver plays an integral role in carbohydrate, protein, lipid, and bile metabolism. It is also responsible for protein synthesis. Albumin is the most abundant plasma protein produced by the liver.
- Drug and toxin excretion is carried out by the hepatocytes by first polarizing the molecules then conjugating them to make them more hydrophilic. Drugs excreted in the bile may be reabsorbed through enterohepatic circulation leading to prolonged effects.
- Standard laboratory panels used to evaluate the hepatobiliary system help define broad categories of hepatobiliary pathology: hepatitis, hepatobiliary dysfunction, or insufficient protein synthesis. Specific diagnoses often require clinical context and radiologic studies.
- Cirrhosis is the result of chronic hepatic disease and can ultimately result in portal hypertension and liver failure. Liver failure can lead to significant dysfunction in all organ systems, giving rise to coagulopathy, thrombocytopenia, hyperdynamic circulation, esophageal varices, hepatic encephalopathy, hepatopulmonary syndrome, portopulmonary hypertension, and hepatorenal syndrome. The definitive treatment for hepatic failure is liver transplantation.
- Volatile anesthetics reduce mean arterial pressure and cardiac output, leading to a reduction in portal blood flow in a dose-dependent manner. The hepatic arterial buffer response is preserved with isoflurane, sevoflurane, and desflurane leading to the preservation total hepatic blood flow, but not with halothane.
- Advanced liver disease impairs the elimination of many drugs including vecuronium, rocuronium, morphine, meperidine, and benzodiazepines. Dosing should be adjusted in the setting of liver failure.
- Elective surgery is contraindicated in patients with acute hepatitis or liver failure. Patients with chronic hepatitis can safely undergo elective surgery. Hepatotoxic drugs should be avoided and hepatic perfusion maintained. Child-Turcotte-Pugh class and Model for End-Stage Liver Disease score can be used to predict risk of perioperative mortality.

Anatomy of the Liver

The liver is the second largest organ in the human body and is responsible for a host of functions to maintain homeostasis. The liver acts as the interface between the gastrointestinal tract and remainder of the body. It is responsible for metabolic, synthetic, immunologic, and hemodynamic functions. As a result, hepatic dysfunction has profound effects on all organ systems and introduces significant challenges to anesthetic management. It is therefore essential for the anesthesiologist to have a firm grasp of the anatomy, physiology, and pathophysiology of the liver.

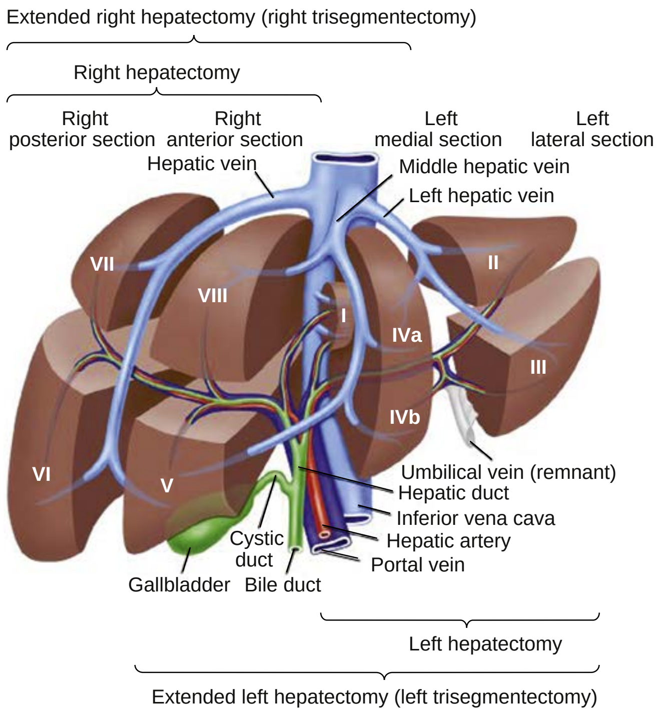

Fig. 16.1 **Schematic depiction of Couinaud segmental liver anatomy and the normal portal venous structures. Bracketed text shows hepatic segments resected during partial hepatectomies.** (Modified from Venook AP, Curley SA. Management of potentially resectable colorectal cancer liver metastases. http://www.uptodate.com/contents/management–of–potentially–resectable–colorectal–cancer–liver–metastases.)

SURGICAL ANATOMY, HEPATIC BLOOD FLOW, AND THE BILIARY TREE

The adult liver can range from around 600 to over 1800 g making the liver one of the heaviest organs in the body. In healthy females the liver ranges in size from 603 to 1767 g,[1] while in healthy males, the liver ranges in size from 968 to 1860 g.[2] In newborns, infants, and children, the liver is also one of the largest organs and the contribution of its weight to total body weight decreases with age. Thus the liver in a term 3 to 3.5 kg newborn can weigh 150 to 170 g,[3] which represents around 5% of the total body weight. In sharp contrast the adult liver represents 2% to 2.5% of the total body weight.

The liver receives approximately 25% of the resting cardiac output (CO).[4] The blood supply is through both the arterial and venous systems in the form of the hepatic artery and the portal vein (Fig. 16.1). The hepatic artery is responsible for 25% to 30% of the blood supply to the liver whereas the portal vein is responsible for 70% to 75%. The hepatic artery arises from the celiac trunk in 80% of the population. In the remainder, it arises from the superior mesenteric artery. After giving rise to the gastroduodenal artery, the common hepatic artery enters the hilum of the liver (porta hepatis) where it further branches into the right and left hepatic arteries, supplying the right and left sides of the liver, respectively. The right hepatic artery gives rise to the cystic artery that supplies the gallbladder.[4] The arteries continue to branch throughout the liver ultimately running through the portal tracts and terminating in the hepatic sinusoids (capillaries). Although part of the venous system, the portal vein is the primary source of oxygenated blood to the liver. The portal vein carries blood from the gastrointestinal tract, pancreas, and spleen to the liver. It drains the superior mesenteric, splenic, and inferior mesenteric veins. It also drains the gastric, cystic, and pancreaticoduodenal veins. The portal vein enters the hilum and, like the hepatic artery, branches into the right and left portal veins, supplying the respective sides of the liver.[4] The portal veins continue to branch throughout the liver in conjunction with the hepatic arteries. As with the arteries, they terminate in the hepatic sinusoids.

Venous drainage of the liver is through the hepatic veins directly into the inferior vena cava (IVC). The right and middle hepatic veins serve the right half and middle portions of the liver, respectively, while the left hepatic vein drains the left half of the liver. The biliary system removes bile from the liver and delivers it to the duodenum through the ampulla of Vater. The intrahepatic bile ducts typically travel with the portal veins, draining into right and left collections systems that ultimately form the common bile duct (CBD; see Fig. 16.1).[4]

From a historical perspective, the description of the gross anatomy of the liver has evolved from being rooted in the surface anatomy of the organ to its functional organization. Traditionally, the liver was divided into four lobes based on its surface features: right lobe, left lobe, quadrate, and caudate. The right and left lobes were divided by the falciform ligament, when viewed anteriorly. When viewed from below, the quadrate lobe was bounded by the porta hepatis posteriorly, the gallbladder fossa on the right, and the ligamentum teres on the left.[4] The caudate lobe was bounded by the porta hepatis anteriorly, the IVC on the right, and the ligamentum venosum fissure on the left. In the late 1800s, Sir James Cantlie demonstrated that the right and left hemilivers were defined by independent portal circulations and thus the functional midline of the liver was at the bifurcation of the portal vein, along a line connecting the gallbladder bed and the IVC ("Cantlie's line"), lateral to the falciform ligament. Cantlie recognized that the line defined a vascular watershed and described its implications for surgical resection of the liver.[5] With advances in hepatic surgery, anatomic descriptions of the liver were developed that further divided the hemilivers into segments based on the vascular distribution and biliary drainage. Each segment has its own independent vascular inflow and outflow, and biliary drainage. As a result, surgical resection of a segment does not compromise adjacent segments. The most commonly used organizational system was developed by Couinaud (see Fig. 16.1).[6] In the Couinaud model, the liver is divided into eight segments. The right and left hemilivers are divided at the bifurcation of the portal vein, along the middle hepatic vein. The right, middle, and left hepatic veins divide the liver vertically into four sectors: right posterior, right anterior, left medial, and left lateral sectors. The four sectors are divided in the horizontal plane by the branches of the portal vein, giving rise to the eight segments. In this system, the caudate lobe is referred to as segment 1 and the remainder of the segments are numbered in a clockwise fashion. Segments 2 and 3 are medial to the left hepatic vein, with segment 2 superior to segment 3. Segment 4 lies between the middle and left hepatic vein and is subdivided into 4a (superior) and 4b (inferior) subsegments. Segments 8 (superior) and 5 (inferior) are located between

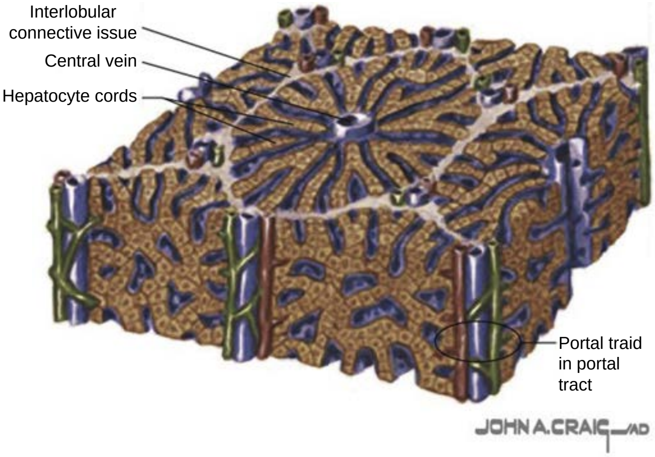

Fig. 16.2 Hepatic lobule. Liver arranged as a series of hexagonal lobules, each composed of a series of hepatocyte cords (plates) interspersed with sinusoids. Each lobule surrounds a central vein and is bounded by six peripheral portal triads (low magnification).

the middle and right hepatic veins. Segments 6 (inferior) and 7 (superior) are located between the right hepatic vein and the edge of the liver.[6] In clinical practice, contrast-enhanced computed tomography (CT) scanning and intraoperative ultrasound are used to define the anatomy unique to each individual and plan for the appropriate resection. To standardize the nomenclature used to describe hepatic resections, the International Hepatopancreatobiliary Association published consensus terminology in 2000 based on the Couinaud segments, known as the Brisbane 2000 terminology.[7] This system of terminology has gained traction but has not yet been uniformly adopted.[8,9]

CELLULAR ANATOMY

Liver Lobule and Acinus

The cellular architecture of the liver supports its functions of detoxifying the blood and metabolizing nutrients. Histologically, the liver parenchyma can be organized into anatomic units (liver lobules) or functional units (liver acinus). The liver lobule is the basic structural unit of the hepatic parenchyma (Fig. 16.2). The lobule typically appears hexagonal in shape with a portal canal at each corner and a hepatic venule (central vein) located in the center. Through each portal canal run the lymphatics, nerve fibers, and a portal triad. Each portal triad consists of a bile ductule, hepatic arteriole, and portal venule. From a functional standpoint, the acinus is the smallest unit of the liver (Fig. 16.3A). It is comprised of a portal tract at the center with central vein at the periphery. Oxygenated and nutrient-rich blood flows from the portal triads to the central hepatic veins through the hepatic sinusoids (see Fig. 16.3B). The walls of the sinusoids are composed of sinusoidal endothelial cells (SECs) that are separated by fenestrations of 50 to 150 nm in diameter. The fenestrations allow the passage of metabolites, plasma proteins, pharmaceutical molecules, lipoproteins, and other solutes into the space of Disse (SD) surrounding the sinusoids while retaining blood cells in the vessels. Larger macromolecules and potentially immunogenic peptides enter the SD by transcytosis through the SECs.[10] Once in the SD, the molecules are taken up by hepatocytes.

Hepatocytes

Hepatocytes make up 75% to 80% of the total cellular volume of the liver.[11] They are responsible for drug, protein, carbohydrate, lipid, and heme metabolism in addition to the synthesis of a variety of proteins necessary for the maintenance of homeostasis at baseline and in response to acute insults secondary to ischemia-reperfusion, viral and bacterial infections, and toxins. Hepatocytes are polarized with heterogenous plasma membranes to facilitate their varied functions. The basolateral (sinusoidal) portion of the membrane is in direct contact with the SD while the apical portion of the membrane makes up the bile canaliculus that drains bile to the ductules.[12] Hepatocytes are divided into different zones based on their proximity to the portal triad. Zone 1 is periportal, zone 3 is around the central vein (perivenous or pericentral), and zone 2 is in between (midzone). Zone 3 hepatocytes are furthest away from the portal tracts and thus receive blood with a lower oxygen tension and nutrient content.[13] The metabolic functions of the hepatocytes differ based on the zone in which they are located (see Fig. 16.3C). This metabolic zonation increases the efficiency of carbohydrate, amino acid, lipid, and xenobiotic metabolism. Periportal (zone 1) hepatocytes are the major sites of aerobic metabolism, and process such as glycogen synthesis and sulfation whereas perivenous (zone 3) hepatocytes are the major sites of anaerobic metabolism, glycolysis, and glucuronidation. By virtue of their location, zone 3 hepatocytes are most sensitive to hypoxia.[13]

Hepatic Stellate Cells

Hepatic stellate cells (HSCs) make up 8% to 10% of all resident liver cells.[14] These specialized cells reside in the SD between liver sinusoidal endothelial cells (LSECs) and the hepatocytes. In the normal liver, HSCs are believed to be in a quiescent state. In the setting of liver injury, these cells become activated in response to cytokines and chemokines generated by hepatocytes, LSECs, as well as leukocytes and Kupffer cells. The stellate cells proliferate and differentiate into myofibroblasts participating in hepatic inflammation and fibrosis.[15]

MYELOID CELLS

The myeloid cells that can be found in the liver consist primarily of Kupffer cells (20%-30%) also known as resident tissue macrophages, in addition to dendritic cells and myeloid-derived suppressor cells. At first glance, it may seem that these cells have a less important role than hepatocytes and LSEC. However, while Kupffer cells constitute around 20% to 30% of nonparenchymal cells, they constitute 80% to 90% of all tissue macrophages.[16] Kupffer cells reside in the portal and lobular liver sinusoids where they engulf both infectious and noninfectious particles by phagocytosis. Once phagocytosed, these particles are unable to induce proinflammatory responses in the liver. Thus by prevalence and location, these cells serve critical roles in innate and adaptive immunity by detoxification where they down-regulate potentially proinflammatory triggers that could disrupt hepatic homeostasis.[17]

Dendritic cells and myeloid-derived suppressor cells are the least abundant of myeloid cells. Hepatic dendritic cells are present in the normal liver and reside in the portal area and are believed to promote tolerance to phagocytosed

particles.[18] Hepatic myeloid-derived supressor cells suppress immune response in the liver. In acute hepatitis they reduce inflammation and limit tissue injury. Their immune suppressive function has been associated with adverse effects in certain pathologic conditions. In chronic viral hepatitis, they may promote viral persistence. They have also been associated with suppression of immune response to hepatic tumors.[17]

LYMPHOCYTES

Cells of lymphatic origin that can be detected in the liver include natural killer (NK) cells, NK T cells (NKT), mucosal-associated invariant T cells, and γδ T cells in addition to major histocompatibility restricted CD4+ T cells, CD8+T cells, and B cells. These cells are distributed throughout the liver parenchyma and serve critical roles in the innate (NK, NKT, mucosal-associated invariant T cells, and γδ T cells) and adaptive (major histocompatibility restricted CD4+ T cells, CD8+T cells, and B cells) immune responses. These cells work primarily to maintain hepatic homeostasis by promoting tolerance to foreign substances. However, when necessary, these MHC-restricted cells can promote the clearance of foreign substances by expanding in response to them while recruiting additional cells from extrahepatic sources such as the lymph nodes and the spleen.[17]

TABLE 16.1 List of Well-Known Substrates, Inhibitors, and Inducers for Phase I, II, and III Metabolism Pathways

Enzymes	Substrates	Inhibitors	Inducers
PHASE I			
CYP3A	Midazolam, buspirone, felodipine, lovastatin, eletriptan, sildenafil, simvastatin, triazolam	Ketoconazole, clarithromycin, itraconazole, saquinavir, fluconazole, grapefruit juice, tipranavir/ritonavir	Phenytoin, rifampin, St. John's wort, efavirenz, etravirine, nafcillin, prednisone
1A2	Alosetron, caffeine, duloxetine, melatonin, ramelteon, tacrine, tizanidine	Ciprofloxacin, enoxacin, fluvoxamine, oral contraceptives, phenylpropanolamine,	Montelukast, phenytoin, smoking components of cigarettes
2C8	Repaglinide, paclitaxel	Gemfibrozil, fluvoxamine, ketoconazole, trimethoprim	Rifampin
2C9	Celecoxib, warfarin, phenytoin	Amiodarone, fluconazole, miconazole, oxandrolone, capecitabine, etravirine, fluvastatin, metronidazole, sulfinpyrazone, tigecycline	Carbamazepine, rifampin, aprepitant, bosentan, phenobarbital, St. John's wort
PHASE II			
UGTs	Bilirubin, phenols, estradiols, opiates, and carboxylic acids	Paclitaxel, midazolam, cyclosporine A, ketoconazole, phenobarbital, and phenytoin	Bilirubin, phenobarbitone, rifampin
SULTs	Phenols, alcohols, and amines	Flavonoids, mefenamic acids, salicylic acids, clomiphene, and danazol	Retinoic acid, methotrexate
NATs	Para-aminobenzoic acid, para-aminosalicylic acids, para-aminoglutamate, sulfamethazine, isoniazid, hydralazine, and sulfonamides	Caffeic acid, esculetin, quercetin, genistein, scopoletin, and coumarin	Androgens, aminophylline
GSTs	Epoxides, quinone, sulfoxides, esters, and peroxides	Phenols, quinone, vitamin C derivatives, dopamine, and *trans*retinoic acid	Extracts of broccoli, cabbage, Brussels sprouts, and grapefruit
PHASE III			
P-gp	Digoxin, loperamide, vinblastine, talinolol	Amiodarone, azithromycin, cyclosporine, diltiazem, dronedarone, erythromycin, itraconazole, ketoconazole, lopinavir/ritonavir, quinidine, verapamil	Avasimibe, carbamazepine, phenytoin, rifampin, St John's wort, tipranavir/ritonavir

Hepatic Physiology

DRUG METABOLISM

The vast majority of drugs used in the conduct of anesthesia are metabolized in the liver. A variety of enzymes convert drug molecules into more water-soluble (hydrophilic) molecules or compounds to facilitate their excretion. These enzymes are designated as being either part of the Phase I pathway or Phase II pathway based on the types of reactions they mediate. Phase I enzymes consist of the cytochrome P450 family of enzymes that convert lipophilic drug molecules to hydrophilic molecules primarily through oxidation, reduction, or hydrolysis. Non-CYP450 enzymes include monoamine oxidases, alcohol dehydrogenases, and aldo-keto reductase. The phase II pathway consists of the conjugation of the products of the phase I pathway with hydrophilic endogenous moieties to make them more water-soluble. Polar molecules may undergo Phase II metabolism without having undergone Phase I metabolism. The most common Phase II reaction is glucuronidation, which is the conjugation of the drug compound to glucuronic acid. This reaction is carried out by a family of enzymes known as uridine 5′-diphospho-glucuronosyltransferases. Other Phase II enzymes include sulfotransferases (SULT), glutathione S-transferases (GST), and catechol O-methyltransferases.[19] The phase III pathway involves the excretion of compounds into the sinusoids or canalicular bile by molecular transporters that are transmembrane proteins which facilitate the movement of large or ionized molecules across cell membranes. The majority of these transmembrane proteins are part of a superfamily of ATP-binding cassette (ABC) transporters that use ATP to actively transport molecules. Common ABC-transporters include multidrug resistance protein (MDR), cystic fibrosis transmembrane conductance regulator, and multidrug resistance–related protein (MRP).

Some orally administered medications undergo extensive metabolism in the gut or liver prior to entering the systemic circulation. This metabolism is termed the first-pass effect and is responsible for the lower oral bioavailability of these medications.[20]

Drug metabolism is affected by a number of factors including genetic polymorphisms of metabolic enzymes, age, gender, pregnancy, liver disease, and concomitantly administered medications. The expression and function of Phase I and Phase II enzymes are reduced in neonates. The activities of some CYP450 enzymes are increased in women compared to men. Genetic polymorphisms in drug metabolizing enzymes and transporters can lead to wide variations in the pharmacokinetics of some drugs such as warfarin, with some patients having lower rates of metabolism based on the specific CYP450 polymorphism they carry. The concomitant administration of medications may also influence drug metabolism. A number of commonly encountered medications can serve as inducers or inhibitors of the enzymes involved in the different phases of drug metabolism.[20] Table 16.1 lists some of the commonly used drugs, which are metabolized and excreted by each of the three phases along with drugs that may serve as inhibitors or inducers for each phase.

See the pharmacokinetics chapter for further discussion of hepatic extraction ratio.

PROTEIN METABOLISM

The liver is responsible for the synthesis and catabolism of proteins, amino acids, and peptides. It is the site of synthesis for 80% to 90% of the circulating proteins including hormones, coagulant factors, cytokines, and chemokines. As such it plays a significant role in the functioning of the body. Albumin is the predominant protein produced by the liver, accounting for over 50% of total plasma protein. It functions to transport lipids and hormones and maintain blood volume. The liver plays a central role in protein degradation. Amino acids are catabolized through one of two reactions: deamination or transamination. Both reactions lead to the production of ammonia, which the liver converts to urea through the urea cycle. Urea is then excreted by the kidneys in the urine.[21]

CARBOHYDRATE METABOLISM

The liver is primarily responsible for storing and releasing glucose to meet the body's needs. In the postprandial state, the liver stores glucose through glycogenesis. Once the glycogen stores are complete, the liver converts excess glucose into fat through lipogenesis. In the fasting state, the liver provides the body with glucose by breaking down glycogen (glycogenolysis) or by generating glucose from carbohydrate precursors (gluconeogenesis).[22]

LIPID METABOLISM

The liver plays an important role in lipid metabolism. Nonesterified fatty acids can arise from the lipase-mediated breakdown of complex lipids, or from thioesterase-mediated hydrolysis of fatty acid-CoA.[23] These fatty acids can enter the liver following oral intake or they can enter the liver following the breakdown of adipose tissue. In the liver, fatty acid oxidation is regulated by two main factors: the supply of fatty acids to the liver (via lipolysis), and the amount of microsomal esterification that occurs.[23] Lipid metabolism is also influenced by the carbohydrate metabolism, as the acetyl-CoA formed during carbohydrate metabolism can be utilized to synthesize fatty acids. Fatty acids can undergo biotransformation to supply energy for the needs of the body. Alternatively, the liver can convert amino acids and intermediate products of carbohydrates into fats and transport them to the adipose tissues.

BILE AND ENTEROHEPATIC CIRCULATION

The adult liver produces approximately 400 to 600 mL of bile each day. Bile facilitates the excretion of toxins as well as the absorption of dietary fats. It is the mechanism of excretion for compounds with molecular weights greater than 300 to 500 Daltons that are not readily excreted by the kidneys. It is used to excrete a host of endogenous and exogenous compounds, including bile acids, bilirubin, phospholipids, cholesterol, drugs, toxins, steroid hormones, and water-insoluble porphyrins. Box 16.1 lists drugs, chemicals, and their metabolites that are excreted in the bile. The other major function of bile is to assist in the digestion and absorption of dietary fats, cholesterol, and vitamins.[24] Bile is 95% water by volume, with the remainder consisting of bile acids, phospholipids, cholesterol, bilirubin, as well as other exogenous and endogenous substances. The two primary bile acids are cholic acid and chenodeoxycholic acid. Bile acids are synthesized by hepatocytes from cholesterol. They are then conjugated to reduce hepatotoxicity and increase solubility and secreted into the canaliculi. The canaliculi drain into the biliary ductules, which connect to form hepatic ducts. The walls of the intrahepatic bile ducts are made up of cholangiocytes that modify the volume and composition of the bile. The ducts ultimately form the left and right hepatic ducts, which join into the common hepatic duct. Bile is stored and concentrated in the gallbladder, which connects to the biliary tree through the cystic duct. The common hepatic duct and cystic duct join to form the CBD, which connects to the duodenum through the sphincter of Oddi (hepatopancreatic sphincter).[24] Following the ingestion of food, fatty acids in the duodenum stimulate the release of cholecystokinin (CCK) which causes the gallbladder to contract and the sphincter of Oddi to relax leading to the release of bile into the duodenum. The bile acids

emulsify dietary fats and facilitate their absorption. The vast majority (95%) of the bile acids released into the duodenum are reabsorbed in the terminal ileum and returned to the liver to be reused. This pathway for recycling bile acids is known as the enterohepatic circulation (EHC).[25] Enterohepatic cycling can impact the pharmacokinetics and pharmacodynamics of drugs that undergo biliary excretion by increasing their bioavailability, reducing their elimination, as well as altering their plasma concentration curves. The effect of EHC on the properties of a drug depends on the physiologic activity of the excreted form of the drug (i.e., prodrug or activated form), the ease with which the excreted form is reabsorbed through the intestines, and whether it is recycled through the liver into the bile or the systemic circulation. In the case of some drugs, EHC can lead to secondary and tertiary peaks in plasma concentration as the drug is recycled into the system.[26]

ROLE OF THE LIVER IN COAGULATION

The liver plays a significant role in the coagulation system. It synthesizes all coagulation factors except factors III (thromboplastin), IV (calcium), and VIII (von Willebrand factor [vWF]). It also synthesizes proteins that regulate coagulation and fibrinolysis such as protein S, protein C, plasminogen activator inhibitor, and antithrombin III. Furthermore, it removes activated clotting and fibrinolysis products through the hepatic reticuloendothelial system. A number of factors require vitamin K to become active. Coagulation factors II, VII, IX, X, as well as protein C and protein S undergo posttranslational modification with vitamin K to become active. Briefly, glutamic acid in the amino terminus of these proteins is converted to gamma-carboxyglutamic acid. These gamma-carboxylated procoagulants can then bind calcium ions and form bridges to phospholipid surfaces that are essential for the formation of activation complexes.[27] Warfarin acts by inhibition gamma-carboxylation. In addition to these vitamin K–dependent factors, hepatocytes also synthesize factor V, XIII, fibrinogen, antithrombin, α_2 plasmin inhibitor, and plasminogen.[28] Thrombomodulin, tissue plasminogen activator, tissue factor plasma inhibitor, vWF, and urokinase are not synthesized in the liver. Instead these proteins are synthesized in endothelial cells, whereas urokinase is expressed by endothelial cells, macrophages, and renal epithelial cells. Tissue plasminogen activator is primarily removed from the bloodstream through the hepatic reticuloendothelial system.[29]

HEME METABOLISM, BILIRUBIN, AND PORPHYRIAS

The liver is involved in both heme synthesis and metabolism. Eighty to 90% of heme synthesis takes place in the bone marrow with the resultant heme used to produce hemoglobin. Most of the remainder of the heme is produced in the liver and used primarily to synthesize cytochrome P450 enzymes. Whereas the rate of heme synthesis in the bone marrow is a function of the availability of iron, the rate of synthesis in the liver is a function of the available free heme pool in the body.[30] Heme is synthesized through an eight-step enzymatic cascade known as the Shemin pathway. Synthesis begins with glycine and succinyl CoA and proceeds through porphyrinogen intermediaries. A deficiency in any of the enzymes involved in heme synthesis leads to the development of porphyria. The specific type of porphyria and its clinical manifestations depend on the specific enzyme that is deficient and the substrate that accumulates as a result. The most common porphyria is acute intermittent porphyria with an estimated incidence of 5 to 10 per 100,000. It is caused by a deficiency in porphobilinogen deaminase, which catalyzes the conversion of porphobilinogen to hydroxymethylbilane. Patients typically have adequate levels of the enzyme for heme homeostasis; however, in response to endogenous or exogenous triggers that induce the Shemin pathway, the capacity of the system is exceeded and they accumulate precursors leading to symptoms. Common triggers include erythromycin, trimethoprim, rifampicin, phenytoin, and barbiturates. Clinical symptoms of an attack include severe, poorly localized abdominal pain (in >90% of cases), nausea, vomiting, agitation, and confusion. Hyponatremia occurs in 40% of attacks. Change in urine color to dark red (especially on exposure to light) is a common finding. Treatment consists of discontinuing the triggering agent, administering pain medication, carbohydrates, and hematin.[30]

Bilirubin is a product of heme catabolism. The primary source is senescent erythrocytes that are phagocytosed by macrophages in the spleen, liver, and bone marrow. The released heme is metabolized by heme oxygenase into bilirubin, yielding carbon monoxide and iron in the process. Unconjugated bilirubin is water insoluble and thus tightly bound to albumin in the circulation. Hepatocytes convert bilirubin into a water-soluble form by conjugating it to glucuronic acid via the enzyme glucuronyl transferase. Conjugated bilirubin is then transported across bile canaliculi and excreted in the bile. In the colon, bilirubin is deconjugated, metabolized by bacteria, and converted into urobilinogen. Urobilinogens are either reabsorbed through the EHC or excreted in the urine and stool, giving urine and stool their characteristic colors.[31]

HEPATIC REGULATION OF HORMONES

The liver can participate in endocrine functions through hormone synthesis or hormone degradation. Hepatocytes synthesize hormones or prohormones such as hepcidin, insulin-like growth factor, and angiotensinogen, respectively. In addition to these hormones, thrombopoietin is also synthesized by hepatocytes and LSECs. These hormones and prohormones have specialized roles in the human body. Thus hepcidin is responsible for iron homeostasis and regulates intestinal iron absorption, plasma iron concentrations, and tissue iron distribution by inducing degradation of the hepcidin receptor, ferroportin.[32] Insulin-like growth factor promotes systemic growth, especially bone growth in children.[33] Angiotensinogen, the precursor of all angiotensin proteins, regulates the systemic blood pressure as well as the water and sodium composition of the body.[34] Thrombopoietin regulates platelet production by stimulating production and differentiation of megakaryocytes.[35] In addition to hormone synthesis, the liver participates in endocrine function by inactivating many hormones, including thyroxine, aldosterone, antidiuretic hormone, estrogens, androgens, and insulin.

TABLE 16.2 Liver Blood Tests and the Differential Diagnosis of Hepatobiliary Disorders

	PREDOMINANT ABNORMALITY		
Blood Test	**Bilirubin Overload (Hemolysis)**	**Hepatocellular Injury**	**Cholestasis**
Aminotransferases	Normal	Increased: May be normal or decreased in advanced stages	Normal: May be increased in advanced stages
Serum albumin	Normal	Decreased: May be normal in acute fulminant hepatic failure	Normal: May be decreased in advanced stages
Prothrombin time*	Normal	Prolonged	Normal: May be prolonged in advanced stages
Bilirubin (main form present)	Unconjugated (also mild increase in conjugates)	Conjugated	Conjugated
Alkaline phosphatase	Normal	Normal: May be increased by hepatic infiltrative disease	Increased
γ-Glutamyl transpeptidase 5′-nucleotidase	Normal	Normal	Increased
Blood urea nitrogen	Normal: May be increased by renal dysfunction	Normal: May be decreased by severe liver disease and normal kidney function	Normal
BSP/ICG (dye)	Normal	Retention of dye	Normal or retention of dye

*Used interchangeably with the international normalized ratio.
BSP/ICG, Bromsulphalein and indocyanine green.

Evaluation of the Liver

CLINICAL ASSESSMENT

There are often no signs or symptoms of liver disease until it is quite advanced. Even then, the only clues may be mild or nonspecific symptoms such as loss of appetite, fatigability, malaise, disrupted sleep patterns, or subtle cognitive changes. Major risk factors for liver disease include: alcohol use; illicit drug use; sexual promiscuity; blood transfusions; exposure to hepatotoxins; prior bouts of jaundice; and a family history of genetic diseases such as hemochromatosis, α_1-antitrypsin deficiency, and Wilson disease. Patients with advanced liver disease may have these nonspecific symptoms, as well as pruritus, easy bruising, and changes in urine or stool color. In advanced liver disease physical examination findings include jaundice, scleral icterus, ascites, spider angiomas, xanthelasma, asterixis, and palmar erythema.

STANDARD LABORATORY TESTS

Standard panels used to evaluate the hepatobiliary system are often called "liver function tests" (Table 16.2).[36] In fact, these tests do not measure specific liver functions. Instead, they help define broad categories of hepatobiliary pathology: hepatitis, hepatobiliary dysfunction, or insufficient protein synthesis.

DETECTION OF HEPATOCELLULAR INJURY

Aminotransferases

Serum alanine aminotransferase (ALT) and aspartate aminotransferase (AST), formerly named serum glutamic-pyruvic transaminase and serum glutamic-oxaloacetic transaminase, respectively, are most commonly elevated because of hepatocellular injury. Both are aminotransferases, enzymes involved in gluconeogenesis. ALT is mainly a cytoplasmic liver enzyme. In contrast, cytoplasmic and mitochondrial isozymes of AST are found in many extrahepatic tissues, including the heart, skeletal muscle, brain, kidney, pancreas, adipose, and blood. Therefore isolated elevations of AST likely represent non-liver sources, but concomitant elevations in AST and ALT usually represent liver injury. Rarely, elevations in AST and ALT levels may result from muscle injury.[37]

Practice guidelines provide recommendations for the evaluation of abnormal liver enzymes, based on the combination of clinical picture and degree of elevation of AST and ALT. Establishing normal reference ranges for AST and ALT have been complicated by studies with heterogeneous populations, since normal ranges differ with gender and body mass index (BMI). Nevertheless, multiple studies show that even mild elevations of AST and ALT above the upper limit of normal are associated with increased mortality. Some clinicians therefore argue that the normal limits should be lowered.[38]

Elevated ALT and AST levels are sometimes described in qualitative terms, ranging from mild (>100 IU/L), to extreme (>2000 IU/L). The extent of aminotransferase elevation can sometimes aid in the differential diagnosis. Mild elevations in AST and ALT can arise from any hepatocyte injury. Large elevations often reflect acute hepatocyte ischemia. Extreme elevations signify massive hepatic necrosis, such as from fulminant viral hepatitis, severe drug-induced liver injury, or shock liver.[51] However, aminotransferase levels do not reliably represent the extent of liver damage. Patients with so called "burnt out" livers, such as from chronic hepatitis, have insufficient functioning hepatocytes to bring about a transaminase increase.

The ratio of AST to ALT may help identify the cause of liver disease. Most causes of hepatic injury are associated with higher ALT than AST levels. However, Wilson disease and alcoholic liver disease are classically associated with an

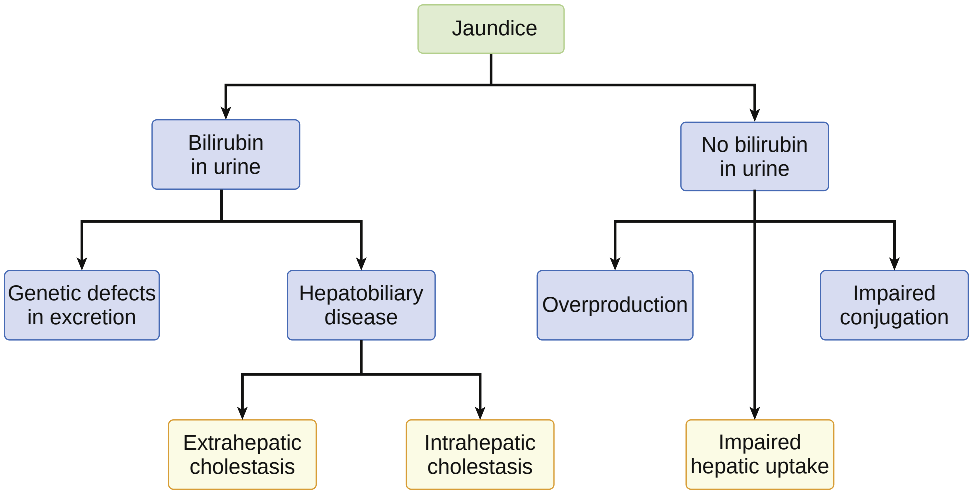

Fig. 16.4 Differential diagnosis of jaundice depending on whether bilirubin is or is not present in the urine.

AST-ALT ratio greater than 1; in some cases, a ratio of 4 has been documented. Chronic hepatitis with minimal fibrosis has a low AST-ALT ratio; however when cirrhosis develops the ratio is greater than 1. Although the AST-ALT ratio may have insufficient predictive value as a sole marker, it can be used in combination with other noninvasive tests to predict the degree of fibrosis in patients with chronic hepatitis.[39]

Lactate Dehydrogenase

Lactate dehydrogenase (LDH) is a nonspecific marker of hepatocellular injury. Extremely elevated LDH signifies massive hepatocyte damage, usually from ischemia or drug-induced hepatotoxicity (such as acetaminophen overdose). These patients will also have extreme elevations in AST and ALT. Elevated LDH concomitant with elevated alkaline phosphatase (AP) suggests malignant infiltration of the liver. Extrahepatic disorders that cause LDH elevation include hemolysis, rhabdomyolysis, tumor necrosis, renal infarction, acute stroke, and myocardial infarction.[37]

Glutathione-S-Transferase

GST is a sensitive test for liver injury, with a half-life (60-90 minutes) much shorter than AST or ALT. Following hepatocyte damage, serum GST rises quickly and serial GST measurements can help monitor for disease recovery.[40] The enzymes AST and ALT are found primarily in periportal hepatocytes (acinar zone 1), whereas GST is present in hepatocytes throughout the acinar zones.[41] Since centrilobular/perivenous hepatocytes are most susceptible to hypoxic injury and acetaminophen toxicity, GST is a useful marker particularly in early stages of injury.

DETECTION OF CHOLESTATIC DISORDERS

Alkaline Phosphatase

AP isoenzymes are present in many tissues, including liver, bone, intestine, and placenta. In the liver, AP is present in the canalicular membranes of the hepatocytes. Mild elevations in AP may be normal, as AP varies with gender, age, blood type, and smoking status.[42] Nonhepatic causes of AP elevation include bone disorders such as Paget disease, osteomalacia, and tumors of the bone; normal growth spurts in children; the third trimester of pregnancy; sepsis; renal failure; and some medications. Elevated AP from a hepatobiliary source is most commonly due to cholestatic disease and typically manifests as an increase to 2 to 4 times the upper limit of normal. Rarely, patients with cholestasis can have extreme elevations in AP (10 times the upper limit of normal).[51] AP will also be elevated to a lesser extent in hepatocellular disease such as hepatitis. The ALT to AP ratio helps differentiate hepatocellular injury (ALT:AP > 5) from cholestatic disease (ALT:AP < 2) from a mixed picture.[38]

AP elevation from cholestasis could be a result of either intrahepatic or extrahepatic biliary obstruction. Common causes include primary biliary cirrhosis, choledocholithiasis, and hepatic malignancy compressing small intrahepatic bile ducts. With a half-life of about 1 week, AP will be normal immediately after the onset of biliary obstruction, and it will remain elevated for days after resolution of obstruction.[37]

The source of AP isoenzyme elevation can be determined by electrophoresis, but this test is expensive and not routinely available. More commonly clinicians confirm the hepatic origin of the AP elevation with other tests that indicate cholestatic disease. The enzymes 5′-nucleotidase and gamma-glutamyl transpeptidase are also elevated in cholestatic disorders, coincident with AP. Simultaneous elevation of these enzymes help identify liver as the source of AP elevation.

Serum Bilirubin

Serum bilirubin is the most commonly used test to monitor for excretory dysfunction of the liver. Bilirubin is measured in serum assays as either direct or indirect bilirubin. Direct bilirubin measures the water-soluble form, which interacts directly with the assay's reagents. While direct bilirubin correlates with conjugated bilirubin levels, and indirect with unconjugated levels, the two terms are not synonymous. The level of unconjugated bilirubin is typically underestimated by the indirect bilirubin test. Distinguishing conjugated from unconjugated bilirubin is key to the differential diagnosis. The presence of bilirubin in the urine can also help differentiate the clinical cause. Bilirubinuria usually reflects conjugated hyperbilirubinemia, since only the water-soluble conjugated form is excreted by the kidney (Fig.16.4).[37]

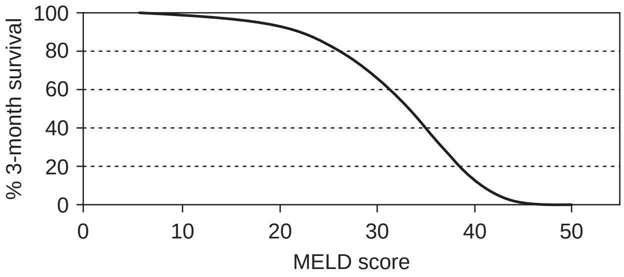

Fig. 16.5 Estimated 3-month survival as a function of the Model for End-Stage Liver Disease *(MELD)* score.

Elevation in the concentration of unconjugated bilirubin is either due to excessive heme breakdown, or the inability of the liver to conjugate bilirubin. One major cause is hemolysis, in which increased erythrocyte breakdown creates more unconjugated bilirubin than the liver is able to conjugate. Massive hemolysis will cause elevations in both forms of bilirubin, but with unconjugated predominance. Gilbert syndrome is a benign condition with genetically low levels of the hepatic enzyme glucuronyl transferase, associated with mild or intermittent elevation in unconjugated bilirubin. Various drugs may also produce unconjugated hyperbilirubinemia. High levels of unconjugated bilirubin are neurotoxic, particularly in infants.

Conjugated hyperbilirubinemia occurs due to either problems with the secretion of conjugated bilirubin from hepatocytes into canalicular bile or to the blockage of bile flow within the hepatobiliary tree. This can be due to a genetic defect in the excretion of bilirubin, or cholestasis (either intrahepatic or extrahepatic). Intrahepatic cholestasis is caused by an inflammatory or infiltrative process compressing small intrahepatic bile ducts, while extrahepatic cholestasis is due to biliary obstruction such as from stones or a pancreatic mass. Primary sclerosing cholangitis (PSC) can involve both intra- and extrahepatic bile ducts.[43]

ASSESSMENT OF HEPATIC PROTEIN SYNTHESIS

Serum Albumin

The serum albumin concentration is used to evaluate chronic liver disease and hepatocellular function (protein synthesis). However, it has poor specificity. Hypoalbuminemia has many other causes besides decreased protein synthesis, including increased catabolism, expansion of the plasma volume, renal losses, and maldistribution of total body albumin. The half-life of albumin in the serum is 20 days. As a result, changes in the synthetic function of the liver are not acutely reflected by the serum albumin concentration. Prealbumin is another protein synthesized in the liver that is also involved in transport and binding. It has a much shorter half-life than albumin. However, the level of prealbumin reflects the status of protein nutrition to a greater degree than liver synthetic function given its high percentage of essential amino acids.[37]

Prothrombin Time

Hepatic synthetic function can also be assessed by measuring the levels of liver-derived coagulation factors. The liver synthesizes coagulation factors in great excess, thus the prothrombin time (PT) will remain normal until significant hepatic impairment occurs. Coagulation factors have shorter half-lives than albumin, ranging from 4 hours for factor VII to 4 days for fibrinogen. Thus when severe liver dysfunction occurs, PT (or the international normalized ratio [INR]) can reflect acute liver failure more quickly than can albumin. It is also used to monitor for restoration of hepatic function, often improving before other clinical signs of improvement occur. However, prolonged PT/INR is not specific for liver disease. It may also represent vitamin K deficiency, warfarin effect, or a genetic factor deficiency.[37]

TABLE 16.3 Interpretation of Hepatitis B Viral Serologies

Hepatitis B Virus Serologies	Interpretation
Hepatitis B surface antigen (HBsAg)	Acute or chronic infection
Antibody to hepatitis B surface antigen (Anti-HBs)	Immunity due to recovery from infection or vaccination
IgM antibody to hepatitis B core antigen (Anti-HBc IgM)	Previous or ongoing infection
IgG antibody to hepatitis B core antigen (Anti-HBc IgG)	Acute infection
INTERPRETATION OF CONSTELLATION OF RESULTS	
HBsAg NEG Anti-HBs POS Anti-HBc IgG POS	Immune due to recovery
HBsAg NEG Anti-HBs POS Anti-HBc IgG NEG	Immune by vaccination
HBsAg POS Anti-HBs NEG Anti-HBc IgM POS	Acute hepatitis B infection
HBsAg POS Anti-HBs NEG Anti-HBc IgG POS Anti-HBc IgM NEG	Chronic hepatitis B infection
HBsAg NEG Anti-HBs NEG Anti-HBc IgG NEG	Not immune, potentially susceptible

TESTING FOR DIAGNOSIS OF SPECIFIC DISEASES

In addition to the above standard laboratory tests, targeted testing can aid in the diagnosis of specific hepatobiliary diseases. Such testing includes serologic testing for viral and autoimmune diseases, genetic testing, and tumor marker assays. Viral markers, including antibodies, antigens, and genetic material, are used to diagnose hepatitis from hepatotropic viruses (A, B, C, D, and E) and herpesviruses such as cytomegalovirus and Epstein-Barr virus. Patients with acute or chronic hepatitis B infection and those with immunity due to resolved infection or vaccination can be distinguished based on measurements of hepatitis B surface antigens and surface and core antibodies (Table 16.3). HBV DNA testing has also emerged to monitor treatment effect and the development of chronic hepatitis B after resolution of acute hepatitis.[44]

Testing for hepatitis C is recommended for those with various risk behaviors and exposures (such as history of intravenous drug use, long term hemodialysis, or HIV infection) and as part of an evaluation for unexplained liver disease. American guidelines also recommend one-time screening for hepatitis C in all persons in the United States born between 1945 and 1965, as this birth cohort has the highest prevalence of hepatitis C. Screening entails testing for antibodies to HCV; a positive screen indicates exposure to the virus. Active infection can then be confirmed with nucleic acid testing for HCV RNA. Sustained viral response to treatment is defined as the absence of HCV RNA detected at least 12 weeks after the completion of therapy.[45] Currently, patients also receive HCV genotype testing prior to the initiation of treatment. New direct antiviral agents are highly effective in achieving sustained viral response for most genotypes and most clinical conditions. Therefore genotype testing may soon no longer be routinely required.[46]

Rapid HCV antibody testing and point of care RNA tests are useful in community-based settings serving high-risk populations and remote settings without access to centralized laboratories. The measurement of HCV core antigen (HCVcAg) can diagnose active hepatitis C infection with high sensitivity and specificity as a single test, although it is currently not the standard of care. HCVcAg measurement is particularly useful as a rapid, single test for diagnosis in populations who are at high risk of loss to follow-up. However, it is not yet available as a point of care test.[47]

Markers of hepatic malignancy include alpha fetoprotein (AFP) and protein induced by vitamin K absence or antagonist-II (PIVKA-II).[48-50] AFP is a glycoprotein synthesized in the liver, fetal yolk sac, and GI tract. The normal value of AFP is less than 20 ng/mL. A significantly elevated concentration of AFP, often greater than 1000 ng/mL, is common in patients with hepatocellular carcinoma (HCC). AFP is also elevated in testicular germ cell tumors, and less frequently in prostate and other gastrointestinal cancers. The concentration of AFP is used to monitor HCC disease progression and response to treatment. It is also widely used to screen for HCC in high-risk patients, along with ultrasound. However, AFP's role in HCC surveillance has recently been debated, as studies suggest that AFP has insufficient sensitivity as a screening tool for HCC, particularly for small and solitary tumors. AFP may be normal in 40% of HCC patients.[51,52] PIVKA-II, also known as des-γ-carboxylated prothrombin, is a biomarker for HCC with high specificity.[48,50] With a shorter half-life than AFP, PIVKA-II is useful in monitoring for treatment response and recurrence. PIVKA-II is also associated with worse survival. AFP and PIVKA-II combined can diagnose HCC with further increased sensitivity and specificity.[53]

TESTING IN MANAGEMENT AND PROGNOSIS OF LIVER DISEASE

Laboratory tests can help define the type of liver dysfunction, and even identify specific causes. In addition, some of these markers are used to assess disease severity, monitor disease progression and treatment, and predict mortality. Taken alone, thrombocytopenia is the earliest sign of cirrhosis among the routine serum tests, indicating both decreased hepatic function and splenic sequestration from portal hypertension.[54] Some markers are combined to create scoring systems, thereby improving the sensitivity and specificity of single tests. For example, the Model for End-Stage Liver Disease (MELD) score (a calculation that combines INR, bilirubin, and creatinine) was created to assess risk of mortality in cirrhotic patients undergoing transjugular intrahepatic portosystemic shunt (TIPS) procedures. The MELD score now is used for liver transplant listing, as it correlates with wait-list mortality. Standard tests such as INR, lactate and platelet count, as well as novel quantitative tests have been used to predict short-term outcome after liver transplantation.[55] The HCC-MELD score, which combines AFP, MELD, and tumor size, can predict survival after liver transplantation in HCC patients.[56] Elevated bilirubin predicts poor prognosis in acute or chronic liver disease, and AP and bilirubin together predict poor outcome in primary biliary cirrhosis.

Noninvasive Serum Testing for Fibrosis

Multiple models combining noninvasive measurements have been used to assess the severity of fibrosis. The goal of these models is to allow for disease staging (from mild fibrosis to cirrhosis) without requiring liver biopsy. Although liver biopsy remains the diagnostic gold standard, limitations include sampling error, subjectivity in interpretation, pain, bleeding, and cost.[54] These models include various combinations of standard tests such as aminotransferases, platelet count, and INR; as well serum markers of extracellular matrix turnover such as alpha-2-macroglobulin, apolipoprotein A1, and hyaluronic acid. New commercial panels test an array of direct markers of collagen turnover, which correlate with fibrosis.[39,57,58]

Quantitative Liver Tests

Quantitative liver function tests can estimate hepatocellular function by measuring the clearance of various substances metabolized by the liver. Two such substances are indocyanine green (ICG) and bromsulphalein. However, clearance techniques are imperfect tests, potentially influenced by extrahepatic uptake or clearance of the substance, changes in blood flow including portosystemic shunting, and other unknown factors. ICG is avidly extracted by the liver and undergoes minimal extrahepatic uptake and metabolism. Its elimination kinetics are expressed in the ICG plasma disappearance rate (PDR). It can be measured noninvasively by a transcutaneous method. The test is even sensitive to early changes in liver function, and it may be used to guide clinical management. By estimating functional hepatocellular mass, it may help predict outcomes after partial liver resections. It is also used as an early test of graft function following liver transplantation. However, like other highly extracted substances, ICG clearance is dependent on hepatic blood flow, and therefore reflects changes in both hepatic blood flow and hepatocyte function. In fact, ICG is also used specifically to test hepatic blood flow as discussed below. A drop in the ICG PDR may represent a reduction in hepatocellular function, a decrease in hepatic blood flow, or both. Bromsulphalein is another highly extracted substance that can be used to measure hepatic clearance. Bromsulphalein has been associated with severe systemic reactions, and therefore is largely no longer used.[59]

The capacity of the liver to metabolize drugs can also be measured by caffeine clearance, galactose elimination, aminopyrine breath test, and monoethylglycinexylidide (MEGX).[37,60-62] Caffeine clearance can be measured noninvasively through metabolites present in the saliva up to 24 hours after oral caffeine intake. MEGX is the primary metabolite of lidocaine and is measured in the serum after intravenous injection of lidocaine. MEGX concentration may be used to estimate liver function after partial hepatectomy and may have prognostic value in intensive care unit patients with liver dysfunction. MEGX was found to independently predict poor outcomes in patients with chronic hepatitis C, and it was more sensitive than standard liver tests in identifying these patients.[63] Expensive and time consuming, quantitative tests currently remain primarily research tools and require further validation.

MEASUREMENT OF HEPATIC BLOOD FLOW

Blood flow to the liver can be measured using clearance techniques, indicator dilution techniques, and direct measurements.

Clearance Techniques

Based upon the Fick principle, clearance techniques estimate the hepatic blood flow by measuring the rate of disappearance of substances that are exclusively and avidly cleared by the liver. Such substances with high extraction ratios include ICG, propranolol, lidocaine, and radiolabeled colloid particles. The primary limitation of clearance techniques is they assume normal hepatocyte function. Hepatic capacity to eliminate these substances can be variably or significantly diminished in liver disease. This is particularly problematic since liver dysfunction and altered hepatic flow are so often linked.[64]

The dual cholate test measures the clearance of cholate, a bile salt, given in both oral and intravenous form. The oral cholate undergoes a high first-pass extraction and allows for a calculation of portal circulation. Clearance from the systemic circulation is measured using the intravenous cholate. One can quantify the degree of portal-systemic shunting and calculate a disease severity index. This index correlates with degree of fibrosis on liver biopsy and can predict risk of cirrhosis and poor clinical outcomes.[63,65]

Indicator Dilution Techniques

Unlike clearance methods, indicator dilution techniques can measure hepatic blood flow even in the setting of liver dysfunction. A known quantity of a radiolabeled indicator (e.g., iodinated albumin) is injected into the portal system and hepatic artery. The concentration of that substance is then measured continuously from a hepatic vein. Hepatic blood flow can then be calculated by creating indicator dilution curves. The substance used should be resistant to hepatic clearance.[4] Indicator dilution techniques also presume uniform liver perfusion, and therefore results could be altered in patients with shunting. These techniques are invasive and are still primarily research tools as well.[64]

Direct Measurements

Blood flow through the portal vein or hepatic artery can be measured directly using electromagnetic or ultrasonic probes. These techniques are invasive and subject to significant error. The surgical procedures required to implant the probes can themselves alter hepatic blood flow. Once implanted, the probes are often left in place, and blood flow is then measured via telemetry. Implantable Doppler probes are sometimes used in patients immediately post-liver transplantation, and in patients who are at high risk for hepatic artery or portal vein thromboses.[64]

RADIOLOGIC METHODS

Radiologic techniques play important roles in diagnosing liver disease. Splenoportography evaluates the splenic and portal veins; it is useful in identifying varices and thromboses. Portal venography uses three-dimensional CT to create vascular maps of portosystemic collateral vessels. These noninvasive imaging techniques are particularly useful in surgical planning, such as before liver transplantation.[66]

Inexpensive and routinely available, ultrasound can help diagnose cirrhosis with high sensitivity and specificity. Ultrasonic signs of cirrhosis include surface nodularity, hepatomegaly, and hypertrophy of the caudate lobe, as well as signs of portal hypertension, such as ascites, splenomegaly, and increased portal vein diameter. Doppler ultrasonography can show diminished portal flow and portal venous flow reversal.[54,67,68] Fibrosis can also be estimated using elastography, a noninvasive measure of liver stiffness (LS). A shear wave is delivered across the liver via an ultrasound probe, and the wave propagation is then measured. Transient elastography is reproducible and easily performed in the office. Magnetic resonance elastography is especially useful in obese patients and those with ascites, where transient elastography is less accurate. Stiffness is a continuous measure which correlates with the histological stage of fibrosis, with high sensitivity and specificity.[67,69,70] The combination of serum tests along with elastography offers much improved accuracy in diagnosing fibrosis. These tests are now widely used in practice, although they have not yet supplanted the role of liver biopsy.

Patients with chronic liver disease and chronic hepatitis B virus carriers are at increased risk for developing HCC and require regular screening for the cancer. Ultrasound is the most widely used screening tool for HCC worldwide. Multiphasic, contrast-enhanced CT and MRI are used to evaluate focal liver lesions suspicious for HCC with high sensitivity and specificity. While normal liver parenchyma receives only 25% blood flow from the hepatic artery (the rest via the portal vein), HCC cells receive their blood supply primarily from the hepatic artery. Contrast-enhanced imaging reflects this fact with HCCs showing hyperintensity in the arterial phase and washout during the portal venous phase. The Liver Imaging Reporting and Data System (LI-RADS) is a standardized tool for the radiologic classification of liver lesions in patients with chronic liver disease. Use of the LI-RADS has improved radiologic diagnostic accuracy and reduced the need for biopsy in these patients. In fact, confirmatory biopsy is rarely used, even prior to liver transplantation for HCC.[54,71,72]

Hepatic Pathophysiology

CHOLESTATIC DISEASE

Cholestasis is the impairment of bile production or flow. Cholestatic disorders are characterized primarily by elevations of serum AP and gamma-glutamyl transferase (GGT), with or without elevations in bilirubin. Cholestasis can present as an acute or chronic condition and is thought to affect up to 20% of the population.[73] The impairment of flow leads to an increase in the concentration of bile salts in the serum and hepatocytes. As the bile salts accumulate in the liver, they dissolve hepatocyte cell membranes, leading to the release of AP and GGT, resulting in an increase in the serum concentrations of these enzymes.[74] Serum concentrations of AST and ALT, which are found in the cytoplasm of hepatocytes, are not increased to as great an extent. As the disease progresses, the serum concentration of conjugated bilirubin increases, giving rise to jaundice.[31] The majority of cases of cholestasis are benign; however, severe and prolonged cholestasis can lead to cirrhosis.

Signs and symptoms of cholestasis include fatigue, pruritus, dark urine, and pale stools. An elevation of AP on screening laboratory studies may be the first indication in asymptomatic patients. The evaluation consists of a history and physical exam followed by abdominal ultrasonography. Abdominal ultrasonography is used to distinguish between extrahepatic and intrahepatic cholestasis. Extrahepatic cholestasis results from mechanical obstruction of the extrahepatic bile ducts, typically by stones, strictures, or masses leading to ductal dilation. Definitive diagnosis and treatment is by endoscopic retrograde pancreatography (ERCP). If the etiology is unclear, further imaging can be conducted using endoscopic ultrasound or magnetic resonance cholangiopancreatography to identify the biliary lesion leading to obstruction.[75] Normal imaging results indicate intrahepatic cholestasis. Intrahepatic cholestasis can have several etiologies including immune-mediated, infectious, drug-induced, paraneoplastic, and ischemic. The first step in the evaluation is the measurement of antimitochondrial antibody (AMA) titers to rule out primary biliary cholangitis (PBC). Further evaluation may require ERCP and liver biopsy.

PRIMARY BILIARY CHOLANGITIS

Formerly known as primary biliary cirrhosis, PBC is an autoimmune disease that is characterized by the destruction of intrahepatic cholangiocytes and the presence of AMAs. It is one of the most common cholestatic liver disorders.[76] Reported prevalence rates vary from 20 to 490 cases per million inhabitants with the highest rates reported in the United States.[77] Over 90% of patients are female and the average age at diagnosis is typically in the sixth decade. The diagnosis is made based on an elevation of AP over 1.5 times the upper limit of normal for a duration greater than 24 weeks along with the presence of an AMA titer greater than 1:40.[76] A liver biopsy in these patients will reveal interlobular bile duct lesions. Up to 60% of patients may be asymptomatic at diagnosis. If present, the most common symptoms at presentation are fatigue and pruritus. A large number of patients may present with other autoimmune disorders such as keratoconjunctivitis sicca and Raynaud phenomenon. PBC may be associated with osteopenia as well as hyperlipidemia.[76] The disease develops as a result of the loss of tolerance to mitochondrial antigens, leading to autoimmune-mediated destruction of biliary epithelial cells (cholangiocytes). PBC can lead to cirrhosis and liver failure, ultimately requiring transplantation.

Treatment consists of ursodeoxycholic acid (UDCA) administration. UDCA, a bile acid, is thought to act by modifying the bile acid pool and reducing inflammation. Approximately 60% to 70% of patients with PBC respond to UDCA with improvement in serum AP and bilirubin levels and a delay in the progression to cirrhosis and liver transplantation. Patients who have a suboptimal response to UDCA have an increased risk of developing complications and liver failure. In these patients, the administration of obeticholic acid, a farnesoid-X receptor agonist, has been shown to reduce the serum levels of AP. Fibrates and corticosteroids have also shown benefit when combined with UDCA in patients who are unresponsive to UDCA alone.[78-83]

PRIMARY SCLEROSING CHOLANGITIS

PSC is a rare cholestatic, immune-mediated disease that occurs most frequently in men aged 30 to 40 years old. It is characterized by inflammation and fibrosis of the bile ducts. The majority of patients with PSC have ulcerative colitis as well. Approximately half of the patients are asymptomatic at diagnosis. The most common presenting symptoms are fatigue and pruritus. Blood tests demonstrate a cholestatic pattern. Patients may also have hypergammaglobulinemia and elevations in serum autoantibodies. Diagnosis is made based on the presence of multifocal strictures and segmental biliary dilations on cholangiography, and the exclusion of a number of other possible etiologies including bacterial cholangitis, choledocholithiasis, and surgical biliary trauma.[84] Patients have an increased risk of developing hepatobiliary carcinoma. The disease is progressive, with biliary fibrosis leading to cirrhosis and ultimately end-stage liver disease (ESLD). Liver transplantation is the only effective therapy.

CIRRHOSIS

Cirrhosis is the common pathologic endpoint of a variety of mechanisms of hepatic injury. In the United States, it is the 14th most common cause of death and has a prevalence of 0.3%.[85] The most common causes of cirrhosis in western countries are alcoholic liver disease, hepatitis C, and nonalcoholic steatohepatitis. In the Asia-Pacific region the most common cause is hepatitis B.[86] The morbidity and mortality associated with cirrhosis result mainly from portal hypertension. Chronic liver disease promotes apoptosis and regeneration of hepatocytes. The resultant inflammation leads to parenchymal injury and fibrosis, causing distortion and obstruction of the hepatic vascular architecture. These structural changes increase hepatic resistance to portal blood flow (PBF) and give rise to portal hypertension. Hepatic vascular resistance is further increased due to hepatic endothelial dysfunction, which results in a reduction of vasodilator (primarily nitric oxide [NO]) production and an increase in vasoconstrictor (i.e., thromboxane) production.[87] Portal hypertension and the release of angiogenic factors lead to the development of gastroesophageal varices as well as portosystemic shunts. As portal hypertension worsens, the locally released NO and prostaglandins cause the splanchnic circulation to vasodilate. This further increases portal inflow and exacerbates portal hypertension. Splanchnic vasodilation also leads to systemic hypotension that, in turn, increases sympathetic tone, activates the renin-angiotensin-aldosterone system, and increases antidiuretic hormone release, leading to the development of ascites and the hepatorenal syndrome (HRS). Other significant complications of cirrhosis and portal hypertension are spontaneous bacterial peritonitis, encephalopathy, HRS, portopulmonary hypertension (PoPH), cirrhotic cardiomyopathy, and HCC.[88]

Laboratory abnormalities in cirrhotic patients include elevations in ALT, AST, AP, GGT, as well as serum bilirubin. Hypoalbuminemia and elevations in the PT are indications of hepatic synthetic dysfunction. Although liver biopsy is the gold standard for diagnosing cirrhosis, it is often not necessary in the presence of an appropriate patient history, and laboratory and radiologic data. In patients who are suspected of having cirrhosis, abdominal ultrasonography is used to aid in the diagnosis and evaluation for HCC and portal hypertension. Serologic studies and ultrasound-based techniques for evaluating hepatic fibrosis are also available.[89]

The risk stratification of patients with cirrhosis is based on the presence and degree of portal hypertension, gastroesophageal varices, and synthetic dysfunction.[90] There are two stages of cirrhosis: compensated and decompensated. Decompensated cirrhosis is characterized by the presence of ascites, variceal hemorrhage, and/or hepatic encephalopathy (HE). Compensated cirrhosis is characterized by the absence of these clinical conditions. While the median survival in patients with compensated cirrhosis is greater than 12 years, in those with decompensated cirrhosis it is approximately 2 years.[91] Patients with compensated cirrhosis can be further stratified based on their degree of portal hypertension. Portal hypertension is defined as a hepatic venous pressure gradient (HVPG) greater than 5 mm Hg. Patients with an HVPG greater than 10 mm Hg are deemed to have clinically significant portal hypertension. They are at increased risk of developing varices, overt hepatic decompensation, postsurgical decompensation, and HCC compared to those with mild portal hypertension (HVPG between 5 mm Hg and 10 mm Hg).[92-94] Although HVPG is the gold standard for monitoring portal hypertension, its invasive nature precludes its routine use. A noninvasive measure of clinically significant portal hypertension is LS using transient elastography, an ultrasound-based approach. An LS value greater than 20 kPa has been shown to effectively discriminate mild from clinically significant portal hypertension.[95] Liver Doppler ultrasound may also aid in the diagnosis. The presence of portosystemic collaterals or reversal of portal venous flow on ultrasound imaging is also sufficient to diagnose clinically significant portal hypertension.[96] In patients with clinically significant portal hypertension, the presence of gastroesophageal varices portends a worse prognosis.[97]

The management of patients with compensated cirrhosis who don't have gastroesophageal varices focuses on preventing the advancement of the disease by treating the underlying etiology.[90] Patients with varices are treated with nonspecific beta-blockers (i.e., propranolol, timolol), carvedilol or endoscopic variceal ligation to prevent variceal hemorrhage. Nonspecific beta-blocker therapy reduces HVPG.[98-100]

Acute variceal hemorrhage is a medical emergency. Management consists of airway protection, volume resuscitation, and endoscopy with variceal ligation. The concomitant initiation of antibiotic prophylaxis (ceftriaxone 1 g/24 h) and vasopressor infusion (somatostatin, octreotide, or terlipressin) has been shown to improve outcome and is the standard of care. Once stabilized, preemptive TIPS may be performed in patients who are at high risk of rebleeding.[90]

ASCITES

The presence of ascites is a marker of decompensated cirrhosis. The 1-year mortality rate of patients who develop ascites is 20%.[100] Patients who develop ascites are at increased risk of developing further complications including spontaneous bacterial peritonitis and acute kidney injury (AKI). Management consists of dietary sodium restriction, nonspecific beta-blocker therapy to reduce portal pressure, and diuretic administration (spironolactone, furosemide). Midodrine can be added for refractory ascites. TIPS can improve transplant-free survival in certain patients with refractory ascites.[86]

Renal Failure and Hepatorenal Syndrome

Up to 40% of patients admitted to the hospital with ESLD develop renal failure. Renal failure is a sign of advanced disease and has a poor prognosis in liver failure. Seventy to 80% of cases are precipitated by hypovolemia or bacterial infections. HRS is less common and associated with a worse prognosis.[101,102] The diagnosis of HRS is one of exclusion. It is characterized by AKI in the absence of any apparent cause (shock, nephrotoxic drugs, obstruction, renal parenchymal disease) that is unresponsive to volume expansion and diuretic withdrawal. AKI is defined as a rise in creatinine greater than or equal to 0.3 mg/dL within 48 hours or a greater than 50% increase from baseline within 7 days.[103] HRS is subcategorized into Type 1 and Type 2 based on the rapidity of onset and degree of injury. Type 1 is rapidly progressive with a doubling of serum creatinine within 2 weeks. It is usually associated with a precipitating factor and has a worse prognosis. The treatment for HRS is aimed at increasing perfusion pressure to the kidneys. For critically ill patients, norepinephrine infusion with albumin boluses can be used. In more stable patients, terlipressin (if available) or midodrine with octreotide is administered along with albumin.[104] Dialysis may be used in the absence of response to medical therapy. Liver transplantation is the definitive treatment for HRS.[105]

HEPATIC ENCEPHALOPATHY

HE is brain dysfunction secondary to hepatic insufficiency or portosystemic shunting. It is a sign of decompensated cirrhosis. It occurs in 30% to 40% of patients with cirrhosis and 50% of patients with portosystemic shunts.[106] The clinical presentation is variable and can range from mild changes in personality to disorientation, somnolence, and coma. Asterixis is usually present in the early to middle stages.[107] The severity of HE is typically graded from I to IV using the West Haven criteria with Grade I indicating mild symptoms and Grade IV, coma (Table 16.4).[108] Common precipitating factors of HE include infections, variceal hemorrhage, and diuretic overdose. Diagnosis is based on the exclusion of other causes of brain dysfunction and the application of clinical criteria. Treatment consists of amelioration of

TABLE 16.4 West Haven Criteria for Grading Hepatic Encephalopathy

Grade	Description
I	Trivial lack of awareness; shortened attention span; disordered sleep
II	Lethargy; behavioral change; asterixis
III	Somnolence; confusion; gross disorientation; bizarre behavior
IV	Coma

Modified from Table 2, Page 719 in: Vilstrup H, Amodio P, Bajaj J, et al. Hepatic encephalopathy in chronic liver disease: 2014 practice guideline by the American Association for the Study of Liver Diseases and the European Association for the Study of the Liver. *Hepatol*. 2014;60:715–735.

precipitating factors and the administration of lactulose, a nonabsorbable disaccharide. Rifaximin can be added on to prevent recurrence.[108]

PULMONARY COMPLICATIONS

Hepatopulmonary syndrome (HPS), PoPH, and hepatic hydrothorax (HH) are pulmonary conditions that can develop in patients with cirrhosis and advanced liver disease. HPS has been reported in up to 30% of patients presenting for liver transplantation evaluation and is associated with increased mortality independent of the severity of liver disease.[109] It is defined as abnormal alveolar to arterial oxygen gradient (≥15 mm Hg) while breathing room air in sitting position. It is caused by intrapulmonary vascular dilation in the setting of cirrhosis. Its severity is determined by the PaO_2: greater than 80 mm Hg is mild, 60 to 80 mm Hg is moderate, 50 to 60 mm Hg is severe, and less than 50 mm Hg is very severe.[110] Patients may present with dyspnea at rest or on exertion. Approximately 25% of patients have platypnea (dyspnea when moving from supine to standing) or orthodeoxia (decrease in PaO_2 more than 5% or 4 mm Hg when moving from supine to standing). In advanced disease, patients may exhibit digital clubbing and cyanosis. Patients can be screened with pulse oximetry ($SpO_2 < 96\%$ on room air) and diagnosed based on PaO_2 values. Contrast-enhanced transthoracic echocardiography (TTE) may demonstrate intrapulmonary vascular dilation. No medical therapy has been shown to change outcome in patients with HPS. Supplemental oxygen is provided to maintain SpO_2 over 88%. Liver transplantation is the only effective treatment.[111] As such, MELD exception points are granted for patients with severe HPS (PaO_2 50-60 mm Hg). Patients with very severe HPS (PaO_2 < 50 mm Hg) have an increased risk for complications and mortality following liver transplantation although this risk may be lower in experienced centers.[111,112]

PoPH is pulmonary arterial hypertension in the setting of portal hypertension.[113] It is found in 5% of patients presenting for liver transplant evaluation and, in the absence of treatment, is associated with a 1-year survival of 46%.[114,115] The diagnosis is made by right heart catheterization showing a mean pulmonary artery pressure (mPAP) greater than 25 mm Hg, pulmonary vascular resistance (PVR) greater than 240 dynes/s/cm^5, and a pulmonary artery wedge pressure less than 15 mm Hg. PoPH is classified as mild (mPAP: 25-35 mm Hg), moderate (mPAP: 35-45 mm Hg), and severe (mPAP more than 45 mm Hg).[110] The pathophysiology of the disease remains to be elucidated. Patients are typically screened using TTE to measure right ventricular systolic pressure (RVSP). Those with RVSP greater than 50 mm Hg undergo right heart catheterization to confirm the diagnosis and determine the degree of PoPH. PoPH is treated with phosphodiesterase-5 inhibitors, prostacyclin analogs, and endothelin receptor antagonists to reduce PVR. mPAP greater than 45 mm Hg is an absolute contraindication to liver transplantation. MELD exception is considered for treatment-responsive PoPH.[110]

HH has a prevalence of 5% to 10% in cirrhotic patients.[116] It develops due to the passage of ascitic fluid from the peritoneal cavity into the pleural space through defects in the diaphragm, most often on the right side. Patients may present with dyspnea, cough, chest discomfort, and hypoxia. Chest radiography and thoracentesis are used for diagnosis. Medical therapy consists of sodium restriction and diuretic administration. Refractory HH is treated with TIPS placement. For patients who have failed TIPS, VATS with pleurodesis is an option.[117]

HEPATOCELLULAR CARCINOMA

HCC is the most common primary liver malignancy and the third most common cause of cancer death globally. It occurs with greater frequency in men than woman and with a higher incidence in Asia and Africa, although the incidence has been increasing in the United States.[118] Chronic liver disease is the most important risk factor for the development of HCC. Hepatitis B, hepatitis C, hemochromatosis, alcohol use, nonalcoholic fatty liver disease, diabetes mellitus, and obesity all increase the risk of developing HCC.[119] Screening is recommended for all patients with cirrhosis at 6-month intervals using ultrasound with or without serum AFP measurement. Masses over 1 cm should be imaged with dynamic MRI or four-phase multidetector CT to make the diagnosis noninvasively. A percutaneous biopsy is obtained for nodules that have nontypical appearance on imaging.[120] Staging is based on the size of the tumor, degree of extension into adjacent structures, presence of metastases, liver function, and the patient's physical status. There is no universally accepted system for staging. The tumor, node, metastasis and the Barcelona staging system (BCLC) are two of the more commonly used systems.[120]

Surgical resection of HCC is the definitive treatment for the disease. However, the diagnosis of HCC is typically made late in the course of the disease. In patients with preserved liver function and a solitary tumor confined to the liver, treatment with surgical resection carries a 5-year survival rate from 40% to 75%.[121] Transplantation may be an option for patients with hepatic dysfunction and tumors confined to the liver that meet certain size criteria.[122] Nonsurgical options for patients who are ineligible for resection or transplantation include radiofrequency ablation, transarterial chemoembolization, and systemic therapy.[120]

HEPATIC EFFECTS OF ANESTHETIC AGENTS

Inhalational Anesthetics

(See also chapter on pharmacokinetics/dynamics of volatile anesthetics.)

The hepatic effects of volatile anesthetics result primarily from alterations in liver perfusion. Total hepatic blood flow (THBF) is the sum of PBF and hepatic arterial blood flow (HABF). Reductions in PBF are matched by increases in HABF to maintain THBF through the hepatic arterial buffer response (HABR).[123] Volatile anesthetics reduce mean arterial pressure (MAP) and CO, leading to a reduction in PBF in a dose-dependent manner. The HABR is preserved with isoflurane, sevoflurane, and desflurane leading to preservation of THBF, but not with halothane.[124-126]

Xenon is an inert gas that can been used as an anesthetic.[127] It has favorable anesthetic properties including a low blood-gas partition coefficient (0.115) and a stable hemodynamic profile.[128,129] Hepatic perfusion during xenon anesthesia has been studied in pigs. In one study using radiolabeled microspheres, there was no difference in hepatic perfusion in pigs anesthetized with xenon when compared to propofol.[130] However, a second study using ICG reported a 17% reduction in portal venous blood flow in pigs anesthetized with a ketamine infusion that received a xenon anesthetic compared to controls. They reported no significant difference in hepatic arterial perfusion or hepatic function.[131] In a porcine model, the use of xenon anesthesia was associated with significantly higher hepatic venous oxygen content when compared with propofol.[132] It is not clear that there are relevant clinical consequences to these findings. The successful use of xenon anesthesia for the conduct of liver transplantation has been reported in a series of four cases.[133]

In general, intravenous anesthetics such as propofol, thiopental, etomidate, and methohexital do not adversely affect the liver. Furthermore, the pharmacokinetic properties of these agents are unchanged in patients with cirrhosis.[134-137] Cirrhotic patients may be more sensitive to their central nervous system depressant effects. Propofol has been found to increase hepatic blood flow and oxygen consumption in both animal and human studies that have measured flow using radiolabeled microspheres, Doppler, and electromagnetic flow meters.[138-141] Studies using ICG clearance to measure hepatic flow, however, have reported that propofol reduced hepatic flow.[142,143] These findings were confounded by the fact that propofol itself interferes with ICG clearance.[141,144] Clinically, propofol has no adverse effect on hepatic function. Midazolam elimination is impaired in liver dysfunction leading to prolongation of sedative effects.[145] Dexmedetomidine elimination is reduced in patients with hepatic impairment, necessitating dose reduction.[146]

In patients with significant cirrhosis, the metabolism of morphine, meperidine, and alfentanil is reduced and their durations of action are prolonged.[147-149] In patients with mild hepatic insufficiency, the pharmacokinetics of fentanyl, sufentanil, and remifentanil are unchanged when compared to normal controls.[150-152]

Reduced levels of pseudocholinesterase in patients with hepatic dysfunction may prolong the effects of succinylcholine and mivacurium.[153,154] The time to recovery from cisatracurium is unchanged as it is subject to Hoffman degradation.[155]

Aminosteroid neuromuscular blocking agents (vecuronium, rocuronium, pancuronium) have a larger volume of distribution in cirrhotic patients. They have a slower rate of onset and a longer duration of action, necessitating judicious dosing and close train-of-four monitoring.[156-158] Sugammadex has been shown to be effective for reversing rocuronium in patients with hepatic dysfunction.[159] The use of neostigmine for reversal is likewise unaffected by the presence of hepatic dysfunction.

Five studies have examined the effect of epidural anesthesia on hepatic blood flow. Four have shown a reduction in hepatic blood flow in response to lumbar or thoracic epidural anesthesia when measured using the PDR of ICG and transgastric hepatic vein Doppler. In one study, blood flow was restored with the infusion of colloid and dopamine.[160-162] Maintenance of MAP with ephedrine or norepinephrine further reduced hepatic blood flow. Unlike these studies, a study by Kortgen et al. found that thoracic epidural anesthesia increased hepatic blood flow when measured by PDR-ICG, whereas lumbar epidural anesthesia resulted in an overall reduction.[163] The clinical significance of these findings is uncertain.

Nonhepatic Surgery in Patients With Liver Disease

The preoperative evaluation of patients with liver disease should determine the severity of the disease and the presence of comorbid conditions associated with hepatic dysfunction. Given the mortality risk, elective surgery is contraindicated in patients with acute hepatitis or acute liver failure.[164] In the absence of cirrhosis and significant hepatic dysfunction, patients with chronic liver disease generally have no increased risk for undergoing elective surgery. Patients with cirrhosis who undergo nonhepatic surgery have a higher incidence of postoperative morbidity and mortality when compared to patients without cirrhosis.[165] A wide range of mortality rates has been reported in the literature (1%-50%), mostly in small, uncontrolled, institutional studies spanning 30 years. Mortality in these patients is a function of the severity of liver disease, its attendant comorbidities, and the type of surgical procedure.[165] The largest study of in-hospital mortality in patients with cirrhosis used data from the Nationwide Inpatient Sample. The outcomes of 22,569 cirrhotic patients undergoing one of four index operations (cholecystectomy, colectomy, coronary artery bypass grafting [CABG], and abdominal aortic aneurysm repair) from 1998 to 2005 were compared to those of 2.8 million control patients. It was found that 4214 of the cirrhotic patients had portal hypertension. Patients with cirrhosis had a three- to eight-fold increase in the risk of in-hospital mortality, depending on the operation, compared to control patients. Mortality risk worsened in those with more severe liver disease, ranging from 12- to 23-fold, depending on the specific operation. The greatest risk was seen in patients undergoing CABG.[166] A Taiwanese study comparing 24,282 cirrhotic patients undergoing major nonhepatic surgery with 97,128 matched control patients found an over two-fold increased risk of 30-day mortality in patients with cirrhosis (1.2% vs. 0.7%). Mortality was further increased in those cirrhotic patients with viral hepatitis, jaundice, ascites, gastrointestinal hemorrhage, and hepatic coma.[167]

In cirrhotic patients undergoing nonhepatic surgery, the Child-Turcotte-Pugh (CTP) and MELD scores have been shown to identify those who are at higher risk of morbidity and mortality.[168-172] The CTP score is calculated based on

TABLE 16.5 Child-Turcotte-Pugh (CTP) Score

	POINTS ASSIGNED		
	1	**2**	**3**
Ascites	Absent	Slight	Moderate
Bilirubin	<2 mg/dL	2-3 mg/dL	>3 mg/dL
Albumin	>3.5 g/dL	2.8-3.5 g/dL	<2.8 g/dL
PROTHROMBIN TIME			
Seconds over control	<4	4-6	>6
International normalized ratio	<1.7	1.7-2.3	>2.3
Encephalopathy	None	Grades 1-2	Grades 3-4
Point total	CTP class	Operative mortality	
5-6	A	2-10%	
7-9	B	12-31%	
10-15	C	12-82%	

The 30-day postoperative mortality predicted by the **Child-Turcotte-Pugh (CTP) score** is based on retrospective studies cited in text. Lower mortality rates have been reported in more recent studies.

From Pugh RN, Murray-Lyon IM, Dawson JL, et al. Transection of the oesophagus for bleeding oesophageal varices. *Br J Surg*. 1973;60(8):646–649. https://doi.org/.

the values of five variables: degree of HE, degree of ascites, INR, serum albumin, and total bilirubin (Table 16.5). The score is then used to classify the patient into one of three groups: Class A (score of 5-6), Class B (score of 7-9), and Class C (score > 10).[173] A higher CTP class is associated with a greater risk of mortality. The mortality risk associated with each CTP class has decreased in more recent studies. In early retrospective series of cirrhotic patients undergoing abdominal surgery, the mortality risks associated with CTP Class A, B, and C were 10%, 30%, and 73% to 82%, respectively.[174,175] In a more recent series of 194 patients undergoing 212 general surgical procedures, 30-day mortality was reported to be 6%, 13%, and 53% for CTP Classes A, B, and C, respectively.[169] The risk has been found to be even lower in patients undergoing laparoscopic procedures (Class A: 2%; Class B: 12%; Class C: 12%), suggesting that improvements in perioperative care and surgical techniques have made surgery safer for patients with cirrhosis.[170] A disadvantage of the CTP score is that the grading of encephalopathy and ascites is subjective. Furthermore, the score doesn't take into account other predictors of operative risk such as the type of surgery or the etiology of the cirrhosis.[176]

As described above, the MELD score, calculated using the patient's INR, serum creatinine, serum bilirubin, and etiology of liver disease (Fig. 16.5) [177] is a validated measure of mortality risk in patients with ESLD and is the basis of the liver allocation system for transplantation.[178] A number of studies have validated the MELD score as a predictor of risk in cirrhotic patients undergoing abdominal, orthopedic, and cardiac surgery.[168,179-181] In a large, retrospective study of cirrhotic patients undergoing major abdominal, orthopedic, or cardiac surgery, MELD score was a predictor for mortality at 30 days, 90 days, 1 year, and 5 years. The 30-day mortality ranged from 5.8% in patients with a MELD under 8 to over 50% in patients with a MELD score greater than 20.[182] The incorporation of serum sodium into the MELD score (MELD-Na) as well as a combination of serum sodium and patient age (integrated MELD or iMELD) have been shown to improve the accuracy of predictions of survival over MELD.[183,184] The use of MELD-Na and iMELD may allow more accurate prediction of mortality following nonhepatic surgery; however more studies are needed.[169,185,186]

Studies comparing the predictive power of CTP to MELD have yielded conflicting results likely due to small sample sizes and differences in primary outcome measures and surgical procedures. Small studies in cardiac and general surgical patients have found the abilities of CTP and MELD to predict postoperative mortality to be comparable.[168,179] A study in cirrhotic patients undergoing extrahepatic abdominal surgery found MELD to be a better predictor than CTP for mortality or hepatic decompensation within 90 days of surgery.[180] A more recent study found neither to be a good predictor for death and hepatic decompensation in cirrhotic patients undergoing elective surgery requiring general anesthesia.[171] It has been suggested that both scores should be used in conjunction with other available patient data when attempting to risk-stratify cirrhotic patients for nonhepatic surgery.[187]

Apart from the severity of cirrhosis and the specific surgical procedure, risk factors associated with increased postoperative morbidity and mortality in cirrhotic patients include emergency surgery, American Society of Anesthesiologists (ASA) physical status classification, the presence of renal insufficiency, male gender, and advanced age.[168,170,188]

In addition to determining the severity of cirrhosis, the preoperative evaluation should determine the presence and severity of comorbidities associated with cirrhosis, including HE, pulmonary disease, cardiac disease, and renal dysfunction (see previous discussion). Preoperative laboratory evaluation should include a complete blood count to evaluate for anemia, thrombocytopenia, and leukocytosis. Additionally, INR, fibrinogen, serum electrolytes, creatinine, glucose, transaminases, bilirubin, and albumin should be measured.

Anesthetic Considerations for Procedures Involving the Liver

Transjugular Intrahepatic Portosystemic Shunt. TIPS placement is a catheter-based, endovascular procedure during which a shunt is created between the portal and hepatic venous systems through the parenchyma of the liver (Fig. 16.6). The goal of the procedure is to reduce portal hypertension.[189] The main indications for TIPS are the secondary prevention of variceal hemorrhage and the management of refractory ascites.[190] During acute variceal hemorrhage in high-risk patients (HVPG > 20), TIPS placement following endoscopic intervention has been shown to be reduce rebleeding.[191] Contraindications to the procedure include congestive heart failure, tricuspid regurgitation, and moderate to severe pulmonary hypertension. During the procedure, a catheter is typically inserted through the right internal jugular vein into a hepatic venous branch. A needle is then passed through the hepatic vein into the portal vein. The tract is dilated and a stent is placed across it. HVPG should be

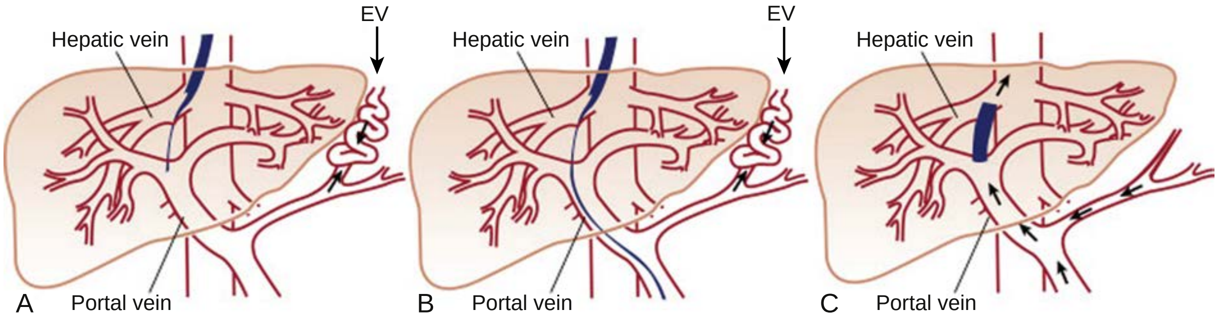

Fig. 16.6 Transjugular intrahepatic portosystemic shunt procedure. A stent (or stents) is passed through the internal jugular vein over a wire into the hepatic vein (A); dilated esophageal varices *(EV)* are apparent. The wire and stent or stents are then advanced into the portal vein (B), after which blood can pass through the portal vein into the hepatic vein and bypass and decompress dilated esophageal veins (C). less than 12 mm Hg following the procedure. The incidence of major complications such as intra abdominal hemorrhage is on the order of 1% to 2%.[192]

TIPS may be carried out electively or emergently. The preoperative assessment should determine the extent of liver dysfunction and associated morbidity. Patients with advanced liver disease may be in a hyperdynamic state. They may have significant ascites with reductions in FRC as well as HH or HPS. Pulmonary function may be further compromised when the patient is in a supine position for the procedure. Patients may also have renal dysfunction, anemia, coagulopathy, and thrombocytopenia. Laboratory studies should screen for anemia, thrombocytopenia, and coagulopathy, as well as hyponatremia and elevations of creatinine and potassium. Patients should be transfused for a hemoglobin concentration less than 7 to 9 mg/dL, INR greater than 2, and a platelet count less than 50,000/μL.[193] The procedure can be conducted under local anesthesia, sedation, or general anesthesia. Consideration should be given to the acuity of the patient, their ability to tolerate supine positioning, and the anticipated length of the case. In patients with significant ascites or recent variceal hemorrhage, general anesthesia with rapid sequence induction for airway protection is preferred. Intraoperative pain may be experienced during the establishment of the intrahepatic shunt and the dilation of the stent. In a series of 150 patients undergoing TIPS with general anesthesia using TIVA, the authors reported a postoperative ICU admission rate of 6.6% primarily for intraoperative hemodynamic instability. They advocated for the use of general anesthesia for all TIPS procedures, given the concerns for airway protection, ability to maintain supine position, and pain associated with the procedure.[194] Postprocedure complications include heart failure due to increased venous return, HE, contrast-induced nephropathy, hemolytic anemia, and sepsis.[195,196]

Hepatic Resection. The most common indications for hepatic resection are for the treatment of secondary metastases (i.e., metastatic colon cancer), primary hepatic malignancies, biliary tract malignancies, and benign hepatic masses.[197] Hepatic resection is carried out along the functional segments of the liver. The liver is divided into eight functional segments based on the distribution of blood supply and biliary drainage. The left liver is comprised of segments II, III, and IV, while the right liver is comprised of segments V, VI, VII, and VIII. Segment I is the caudate lobe (see Fig.16.1). Right hepatectomy involves resection of segments V-VIII. Left hepatectomy involves resection of segments II-IV. Right lobectomy, also described as an extended right hepatectomy or right trisegmentectomy, involves resection of segments IV-VIII with or without segment I. An extended left hepatectomy (left trisegmentectomy) is the resection of segments II-V and VIII.[198] Mortality and morbidity rates are impacted by the extent of the resection. A review of the 4881 hepatic resections over a 5-year period in the American College of Surgeons – National Surgical Quality Improvement Program database reported 30-day mortality and morbidity rates of 1.9% and 13.1%, respectively, for patients undergoing partial hepatectomy. Those mortality and morbidity rates increased significantly for patients undergoing extended hepatectomies (lobectomies or trisegmentectomies) to 5.8% and 22.5%, respectively.[199,200] Other factors which have been shown to impact outcomes are the case volume of the performing center, patient age, history of cardiac, pulmonary or renal disease, blood loss, the presence of ascites, and reduced hepatic function.[199,200]

Laparoscopic hepatic resection is considered most appropriate for small (<5 cm), solitary lesions located in peripheral segments (II-VI), when performed in experienced institutions.[201,202] More extensive resections have been reported in experienced centers. A metaanalysis of 83 comparative case series (2900 patients) found a significantly lower rate of complications, transfusions, blood loss, and hospital stay in case-matched cohort of patients undergoing laparoscopic liver resection compared to open liver resection.[203] To date, the only randomized, controlled trial comparing laparoscopic to open liver resection found a significant reduction in postoperative complications in patients undergoing laparoscopic hepatic resection (19% vs. 31%; 95% confidence interval [CI], 1.67-21.8; $P = .021$) for colorectal cancer liver metastases requiring resection of fewer than three consecutive segments. Although the hospital length of stay was significantly shorter, there were no differences in blood loss or mortality.[204] Conversion from a laparoscopic to an open procedure is usually due to intraoperative hemorrhage and is reported to occur in 6% to 14% of cases. Risk factors for conversion include elevated BMI, increased age, diabetes mellitus, hypertension, and large tumor size.[205,206] A number of recent observational, retrospective studies have described the performance of robot-assisted hepatectomy for both minor and major resections.[207] A metaanalysis of seven studies published between 2010 and 2014, comparing laparoscopic to robotic hepatectomy, found that the laparoscopic approach is associated with significant reductions in blood loss and operative time without any difference in the conversion rate, postoperative morbidity, and the hospital length of stay.[208]

The preoperative evaluation of the patient should focus on determining the severity of liver disease and the presence of other comorbidities. Both cirrhosis and steatosis have been associated with increased mortality in patients undergoing liver resection. The decision to proceed is made based on the anticipated future liver remnant (FLR) that will remain following resection.[209,210] In patients with an anticipated FLR size that is considered unsafe, selective portal vein embolization (PVE) may be conducted in the weeks prior to the hepatic resection. Disruption of portal flow to the diseased portion of the liver leads to atrophy of the portion to be resected and hypertrophy of the FLR, allowing the patient to have adequate liver mass following resection. PVE is typically indicated for patients with an anticipated FLR less than 20% in the absence of cirrhosis, and less than 40% in the presence of cirrhosis.[120,211] Further preoperative evaluation and risk assessment should take place as outlined above. Laboratory investigations prior to hepatic resection should include a complete blood count, serum electrolytes, liver chemistries, albumin, coagulation studies, and a type and screen.

Strategies for Minimizing Blood Loss

Intraoperative blood loss during liver resection is associated with an increased risk of morbidity and mortality.[212-214] Several preoperative factors have been associated with an increased risk of transfusion. These include preoperative anemia, the need for an extrahepatic procedure, the need for caval exposure, major hepatectomy (>3 segments), tumor size, thrombocytopenia, cirrhosis, and a repeat operation.[215-217] For patients at increased risk of significant intraoperative hemorrhage, the use of techniques such as acute normovolemic hemodilution and intraoperative cell salvage have been shown to reduce the transfusion of allogeneic units.[218-221]

A number of strategies have been adopted to reduce blood loss in open hepatic resection and case series from high-volume centers routinely report losses less than 500 mL.[213,222,223] Such strategies include the use of temporary hepatic vascular occlusion and the intraoperative maintenance of low central venous pressure (CVP).[224,225]

Hepatic vascular occlusion techniques may be used by surgeons to limit blood loss by limiting blood flow to the liver. Although not routinely used in simple resections, familiarity with these techniques is important as they may be employed in more complex resections. The most commonly used vascular occlusion technique is occlusion of the hepatic artery and portal vein by clamping the hepatoduodenal ligament. Otherwise known as the Pringle maneuver, total hepatic inflow occlusion was first described in 1908 as a means of controlling hemorrhage in hepatic trauma (Fig.16.7A).[226] The drawback of this maneuver is the potential for hepatic ischemia and reperfusion injury.[227] To mitigate this effect, surgeons typically make use of intermittent clamping with 15- to 20-minute intervals of clamping interspersed with 5- to 10-minute intervals of unclamping for a total ischemic time of less than 120 minutes.[228] Tolerance of longer cumulative ischemic times has been reported.[229] The application of sevoflurane for 30 minutes of preconditioning prior to the Pringle maneuver has been shown in one single-center randomized, controlled trial to significantly reduce postoperative transaminitis and complications in cases with greater than 30 minutes of continuous inflow occlusion.[230] In a subsequent three-armed randomized controlled trial, the same group reported reductions in postoperative transaminitis and complications when sevoflurane was administered after the Pringle maneuver ("post-conditioning") or with the use of intermittent clamping.[231]

The utility of the Pringle maneuver for reducing blood loss in modern hepatic resection has been called into question. While two early randomized, controlled trials showed a significant reduction in blood loss with intermittent Pringle maneuver compared to no inflow occlusion, three, more recent, randomized controlled trials have reported no benefit.[232-236] The median blood loss values reported in these three more recent trials were much lower than those reported in the initial two studies. This finding suggests that in the context of current intraoperative approaches to hepatic resection, the routine use of the Pringle maneuver may not be necessary.[236,237]

An alternative technique that may be utilized is hemi-hepatic inflow occlusion. This maneuver involves exclusively clamping the branches of the portal vein and hepatic artery which supply the hemi-liver which is being resected in order to reduce ischemic injury to the remnant liver (see Fig. 16.7B and C).[238] Hemi-hepatic inflow occlusion hasn't been shown to reduce blood loss when compared to Pringle maneuver.[239-242] Total hepatic vascular exclusion (THVE) involves occlusion of the suprahepatic and infrahepatic IVC in addition to the portal vein and hepatic artery (see Fig. 16.7D)[243] THVE can result in significant hypotension due to the reduction in venous return as well as increased morbidity. It has not been shown to offer any benefit compared to the Pringle maneuver and its use is typically reserved for patients with tumor extension into the IVC. In such complex resections, it has been combined with hypothermic portal perfusion and venovenous bypass to mitigate the risks of hypotension and hepatic ischemia; however the reported mortality is high.[244,245] To avoid the hemodynamic effects of THVE, selective hepatic vascular exclusion (SHVE), which involves clamping the hepatic veins instead of the IVC, may be employed by the surgeon.[246] Some studies have shown that SHVE results in fewer complications than THVE; however it is technically demanding and has a limited role in uncomplicated hepatic resections.[247,248]

LOW CENTRAL VENOUS PRESSURE

While the Pringle maneuver occludes inflow to the liver, retrograde flow through the hepatic veins can still lead to substantial venous hemorrhage. The pressure in the hepatic veins is directly related to vena caval pressure, hence the strategy of maintaining a low CVP (<5 mm Hg) to minimize intraoperative blood loss.[249] Retrospective

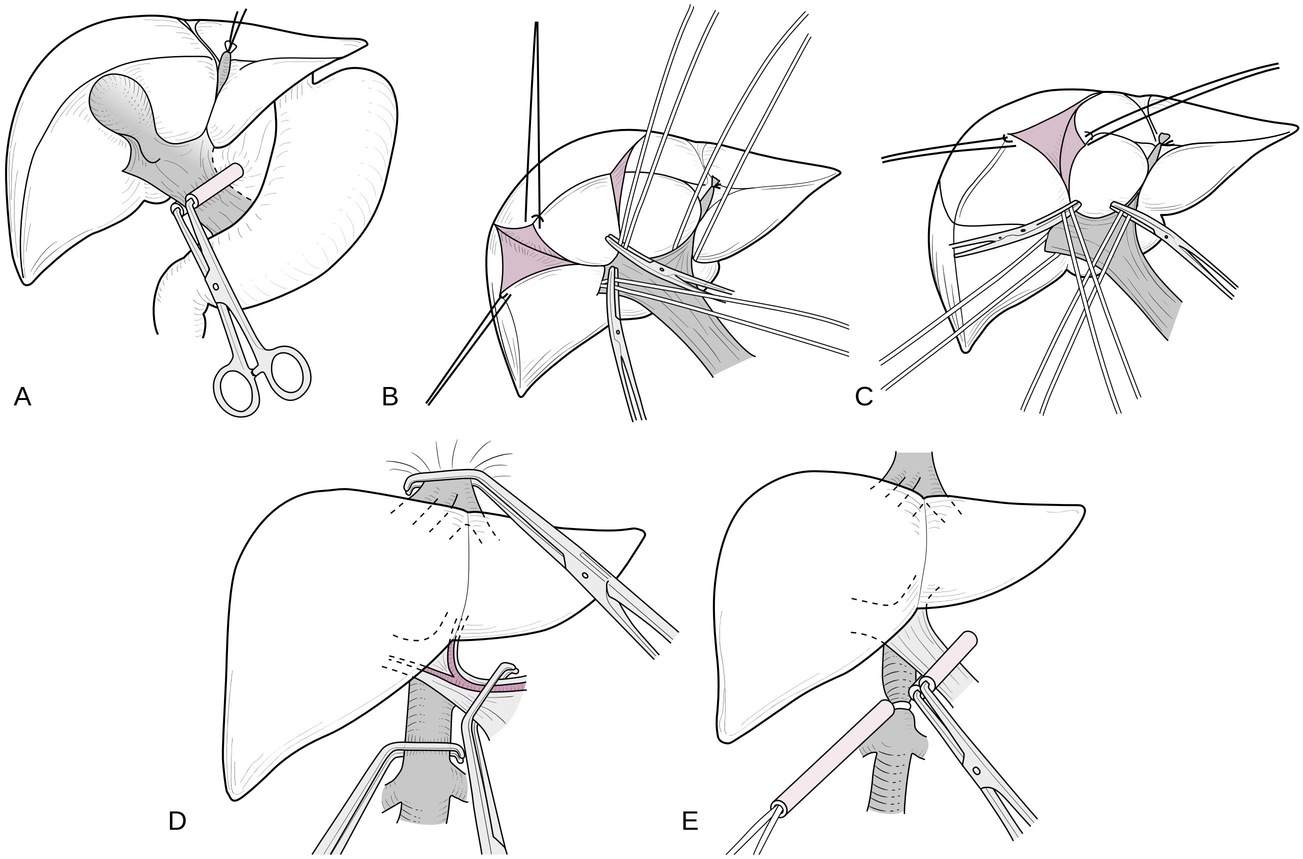

Fig. 16.7 (A–E) Vascular occlusion techniques in hepatic surgery. Surgical vascular occlusive techniques to reduce hemorrhage during hepatic resection include the Pringle maneuver (7A) during which a clamp is placed across the hepatoduodenal ligament to occlude hepatic arterial and portal venous inflow to the liver. Selective hepatic vascular exclusion (7B and C) involves clamping of the vessels perfusing the hemi-liver which is being resected. Total hepatic vascular exclusion (7D) is achieved by clamping the inferior vena cava above and below the liver along with the hepatoduodenal ligament. Another technique combines the application of a clamp across the infrahepatic IVC clamp with one across the hepatoduodenal ligament (7E). *IVC,* Inferior vena cava. (From Otsubo T. Control of the inflow and outflow system during liver resection. *J Hepatobiliary Pancreat Sci.* 2012;19:15–18.)

observational studies have reported reduced blood loss in patients managed with CVP less than 5 mm Hg without any significant adverse events.[250-253] Two randomized controlled trials comparing patients with CVP under 5 mm Hg with liberal volume administration have shown reductions in both intraoperative blood loss and the need for transfusion.[254,255] These studies have all been at risk for significant bias. Furthermore, in some of the trials the difference in estimated blood loss, though statistically significant, was clinically inconsequential.[256] Although standard practice in hepatic resections is to maintain low CVP, some studies have found no association between CVP and intraoperative blood loss. In retrospective studies of patients undergoing donor hepatectomies, no correlation was found between the CVP and intraoperative blood loss. This finding may be due to the fact that living liver donors are healthy patients with normal livers.[257,258] The largest of these studies consisted of over 900 patients. Although it found no correlation between CVP and estimated blood loss, nearly all of the patients were managed with CVPs less than 10 mm Hg, and the majority had CVPs in the 4 to 6 mm Hg range.[258]

A number of techniques have been described for reducing CVP during hepatic resection. The most commonly reported approach is the use of intraoperative fluid restriction with rates of 1 mL/kg/h. Vasopressors are used as needed to maintain SBP over 90 mm Hg and urine output more than 25 mL/h. Though seldom required, vasodilation using nitroglycerin or morphine, or forced diuresis with furosemide, can be instituted if fluid restriction is insufficient.[250,251,254,255,259] The use of milrinone, reverse Trendelenburg position, and epidural anesthesia have also been described, though there is insufficient data to recommend one particular approach.[256,260-262]

Clamping of the infrahepatic IVC (IIVC) has been described as a means of minimizing hemorrhage in the setting of an elevated CVP despite the interventions described earlier (see Fig. 16.7E).[263] A number of randomized controlled trials have demonstrated a significant reduction in blood loss and transfusion with the use of IIVC clamping in patients who tolerate the clamp or have a CVP greater than 5 mm Hg.[262,264-268] A metaanalysis of these trials, comprising of 714 patients, showed a significant reduction in intraoperative blood loss (mean difference −353 mL) with no difference in the rates of postoperative complications. Of note, in pooled analysis, there was no significant difference in reported CVP values between the two groups.[269]

OTHER APPROACHES TO REDUCE BLOOD LOSS

Two multicenter, randomized, placebo-controlled trials have examined the efficacy of prophylactic recombinant Factor VIIa (rFVIIa) administration to reduce transfusion patients undergoing hepatic resection. The studies found no benefit of prophylactic rFVIIa with respect to mortality, red blood cell transfusions, or adverse events.[270,271] A single randomized, controlled trial in 214 patients undergoing primarily minor hepatic resections (82% of cases) found that the administration of tranexamic acid (TXA) resulted in fewer transfusions and less blood loss compared to placebo. In the study group, 500 mg of TXA was administered intravenously prior to incision followed by 250 mg every 6 hours for 3 days.[272]

A recent Cochrane database analysis of 67 randomized clinical trials of methods to decrease blood loss during liver resection found a high risk of bias in all trials. Based on the outcomes that were available in more than one trial, there is low-quality evidence that the "clamp and crush" parenchymal resection technique may be associated with fewer adverse events than radiofrequency resection techniques. They reported very low quality evidence that blood loss, operating time, and total hospital stay were reduced with intraoperative low CVP management.[273]

ANESTHETIC MANAGEMENT

The anesthetic management of these cases should be tailored to the comorbidities of the patients, the surgical approach (open, laparoscopic), the anticipated extent of resection, and the need for vascular occlusive maneuvers. Adequate venous access should be obtained for the anticipated degree of hemorrhage. In cases where significant blood loss is anticipated, red blood cell salvage can be used and consideration should be given to the use of acute normovolemic hemodilution. In addition to standard ASA monitors, intra-arterial blood pressure monitoring should be used in cases during which significant hemorrhage or the need for vascular occlusion maneuvers is anticipated. Central venous catheters may be inserted for both vascular access and CVP monitoring, although some high-volume centers forgo the routine use of CVP monitoring.[274,275] Peripheral venous pressure monitoring may be considered as an alternative. Values are obtained through transduction of an antecubital vein and have been shown to correlate with the CVP in patients undergoing hepatic resection.[276,277] Stroke volume variation (SVV) has been investigated as an alternative to CVP for volume management in patients undergoing liver resection. A study of patients undergoing donor hepatectomy showed an SVV value ≤6% to be predictive of blood loss over 700 mL.[278] In two studies, targeting SVV values greater than 12% to 15% in patients undergoing open or laparoscopic hepatic resection yielded blood loss comparable to, or better than, maintaining low CVP.[279,280] In a study using milrinone to reduce CVP, SVV of 9% yielded a favorable surgical field. No correlation with CVP was noted in this study, possibly due to the lusitropic effects of milrinone.[281] The use of transesophageal echocardiography may be considered in patients with cardiac risk factors, although care must be taken in the presence of significant esophageal varices.

Hepatic resection may be associated with hemorrhage and, in extensive cases, the development of coagulopathy. There is insufficient data to recommend the routine use of viscoelastic hemostatic assays (rotational thromboelastography (TEG) or rotational thromboelastometry). A single randomized, controlled trial of TEG-guided transfusion in cirrhotic patients with coagulopathy (INR > 1.8 and/or platelet count $<50 \times 10^9$/L) undergoing invasive procedures found a significant reduction in blood product administration with TEG compared to the standard lab value–based group. However, only half of the patients enrolled in the trial were undergoing procedures associated with greater than 3% risk of hemorrhage.[282]

With respect to pain management, thoracic epidural analgesia is a highly effective means of pain control for hepatic resection.[283,284] Although its use for this purpose has been described in a number of case series, it remains controversial due to the development of postoperative coagulopathy and thrombocytopenia following hepatic resection and the associated risk of epidural hematoma.[276,285-288] Postoperative coagulopathy and thrombocytopenia occur in 21% to 100% of patients undergoing liver resection, depending on the volume of tissue resected. The INR peaks around postoperative day (POD) one or two while the platelet count is lowest on POD three or four. The values typically return to baseline by POD four or five; however in some patients they may remain elevated for up to a week, leading to delays in epidural catheter removal or the decision to transfuse FFP to facilitate catheter removal.[276,285-289] An additional concern is the accidental dislodgment of the epidural catheter while the patient is coagulopathic which has been reported to occur in up to 7% of patients.[276,286] The degree of coagulopathy is influenced by the extent of the resection. In a review of 759 patients undergoing hepatic resection, the incidence of coagulopathy was 39.1% in patients who had undergone major hepatectomies (>2 segments) versus 21.3% in patients who had undergone minor hepatectomies (≤2 segments).[289] Other factors that are independently associated with postoperative coagulopathy included preexisting cirrhosis, preoperative INR ≥ 1.3, preoperative platelet count <150,000/μL, estimated blood loss ≥ 1000 mL, and the duration of surgery.[285,287,289] Although no case series has reported the complication of an epidural hematoma, epidural hematoma is quite rare and the numbers of published cases may have been inadequate to detect its occurrence.[290,291]

Rapid sequence induction should be considered in patients with significant ascites. Maintenance of general anesthesia has been described with both volatile anesthetics and intravenous anesthetics. There is no compelling clinical evidence for the benefit of one specific agent over another.[292-294] Regardless of the approach, anesthetic dosing should be titrated to the patient's requirements, taking into account the pharmacokinetics and pharmacodynamics of common anesthetic agents in patients with liver disease. The anesthesiologist should understand the vascular occlusion strategies that may be employed during the operation along with their hemodynamic effects. The Pringle maneuver, both during open and laparoscopic hepatic resections, leads to an increase in MAP and systemic vascular resistance and a decrease in CO.[295,296] During open hepatic resection, portal triad clamping leads to a decrease in left ventricular (LV) end-diastolic area (i.e., LV preload). During laparoscopic hepatic resection, in the presence of pneumoperitoneum, PTC also increases LV end-systolic wall stress (i.e., LV afterload).[297]

ENHANCED RECOVERY AFTER SURGERY AND LIVER RESECTION

A number of randomized controlled trials have been conducted comparing the use of enhanced recovery after surgery (ERAS) protocols with traditional management in patients undergoing both open and laparoscopic liver resections.[250,298-301] Although ERAS Society consensus guidelines exist, these trials differed with respect to the number and nature of ERAS elements.[302] Most incorporated preoperative education, early enteral nutrition, and early mobilization. The implementation of an ERAS protocol for liver resection surgery has been shown to reduce minor adverse events, hospital length of stay, hospital cost, and to improve patient quality of life. A metaanalysis published by the Cochrane group found that the use of ERAS protocols resulted in a reduction in mild adverse events, hospital length of stay, and cost. However, all studies were at high risk of bias and the quality of available evidence was determined to be low.[303]

Acknowledgment

The editors and publisher would like to thank Drs. Phillip S. Mushlin and Simon Gelman for contributing a chapter on this topic in the prior edition of this work. It has served as the foundation for the current chapter.

Renal Anatomy, Physiology, Pharmacology, and Evaluation of Function

RICHARD M. PINO and ABRAHAM SONNY

KEY POINTS

- A molecule in the plasma must pass in succession through the endothelial fenestration, glomerular basement membrane (GBM), and epithelial slit diaphragm to cross the filtration barrier and enter the tubular fluid. The capillary endothelium restricts the passage of cells, while the GBM restricts albumin and larger molecules. The negatively charged glycoproteins of the GBM limit the passage of other negatively charged proteins. Thus, the filtration barrier is size selective and charge selective. The epithelial cells maintain the integrity of this capillary bed by producing several key signaling molecules and endocytosis of membrane receptors.
- A primary determinant of glomerular filtration rate (GFR) is glomerular filtration pressure, which depends on renal artery perfusion pressure and the balance between afferent and efferent arteriolar tone. With decreases in afferent arteriolar pressure or blood flow, mediators such as catecholamines, angiotensin II, and arginine vasopressin (AVP) constrict efferent arterioles to maintain glomerular filtration pressure. This is reflected by an increase in GFR.
- Tubuloglomerular feedback is a critical mechanism for renal autoregulation. When GFR is increased, distal tubular NaCl delivery is enhanced and the increase in chloride concentration is sensed by the macula densa to trigger the renin-angiotensin cascade. The result is afferent arteriolar vaso constriction as efferent arteriolar vasoconstriction increases GFR. Autoregulation enables the kidney to maintain solute and water regulation independently of wide fluctuations in arterial blood pressure. Tubular water reabsorption determines urinary flow rate and is closely related to the hydrostatic pressure in the peritubular capillaries. Hypotension of any cause results in decreased urinary flow rate that may be correctable only when arterial blood pressure is restored toward normal.
- The tubule has an enormous capacity for reabsorption of water and NaCl. Each day, 180 L of protein-free glomerular ultrafiltrate is formed, of which almost 99% of the water and 99% of the sodium is reabsorbed. The ability of the kidney to concentrate urine is dependent on the interaction of at least three processes: (1) generation of a hypertonic medullary interstitium by the countercurrent mechanism and urea recycling, (2) concentration and then dilution of tubular fluid in the loop of Henle, and (3) the action of AVP, also known as antidiuretic hormone, in increasing water permeability in the last part of the distal tubule and collecting ducts. The juxtaglomerular apparatus provides an important regulating system for arterial blood pressure, salt, and water homeostasis.
- The interactions of the sympathoadrenal axis, renin-angiotensin-aldosterone system, and AVP will respond to hypotension and hypovolemia by promoting vasoconstriction and the retention of salt and water. Prostaglandins and natriuretic peptides facilitate vasodilation and the excretion of salt and water excretion when there is hypertension and hypervolemia.
- Plasma osmolality is tightly controlled. The threshold for AVP secretion by the neurohypophysis between 280 and 290 mOsm/kg. Even mild dehydration results in rapid antidiuresis, and urine osmolality can increase from 300 to 1200 mOsm/kg. Decreases in intravascular volume stimulate AVP secretion.
- Serum creatinine reflects the balance between creatinine production from muscle and creatinine excretion by the kidney, which is dependent on GFR. Creatinine generation rate varies with muscle mass, physical activity, protein intake, and catabolism. However, when these processes are in equilibrium and renal function is stable, serum creatinine is a useful marker of GFR. The relationship between serum creatinine and GFR is inverse and exponential. A doubling of the serum creatinine implies a halving of GFR.

Introduction

The kidney exemplifies an exquisite structure-function relationship to regulate intravascular volume, osmolality, acid-base and electrolyte balance, and to excrete end products of metabolism and drugs. The kidney also produces hormones involved with fluid homeostasis (renin, prostaglandins, kinins), bone metabolism (1,25-dihydroxycholecalciferol) and hematopoiesis (erythropoietin).[1] In addition to these multiple roles in the healthy patient, almost every systemic disease will affect renal function. This chapter will describe the normal anatomy and physiology of the kidney and the basics for the clinical evaluation of renal function.

Organization of the Kidney

THE NEPHRON

The fundamental unit of the kidney is the nephron (Figs. 17.1 and 17.2). The nephron is composed of a vascular network close to a series of tubules with distinct physiologic functions that empty into collecting ducts to form urine. There are approximately 1 million nephrons in the normal kidney. The kidneys receive about 20% of the cardiac output and are responsible for 7% of total body oxygen consumption, although they account for only 0.5% of the total body weight.[2] Afferent arterioles from the renal arteries branch extensively to supply the renal and peritubular capillaries. Kidney disease can result from perturbations of these vascular, glomerular, and tubular components (see Chapter 42). Knowledge of these factors is important to the anesthesiologist to limit decrements in renal function during the perioperative period.

The kidney is divided into an outer layer, the cortex, which receives 85% to 90% of the renal blood flow (RBF), and an inner medulla (see Fig. 17.1). In the cortex are glomeruli (see Figs. 17.2 and 17.3), tufts of capillaries originating from afferent arterioles. The glomerular capillary endothelial cells have fenestrations that are barriers to red blood cells but allow the transit of plasma proteins and smaller molecules (Fig. 17.4). Their glycocalyx is an anionic barrier that repels large macromolecules and albumin. Knowledge of this is through experimental studies and diseases where albuminuria is seen after alteration of anionic sites in the glomerular basement membrane (GBM).[3,4] During development, these capillaries invaginate epithelial cells to form tufts of visceral epithelial cells with footlike morphologies called podocytes that are rich in actin cytoskeletons. These podocytes anchor to the GBM, closely interdigitate, and envelope the renal capillaries (Fig. 17.5). A thin membrane called the slit diaphragm has an ultrastructural zipper-like complex that spans the space between each of the foot processes of the podocytes.[5] Additional epithelial cells and their extravascular matrix make up the parietal

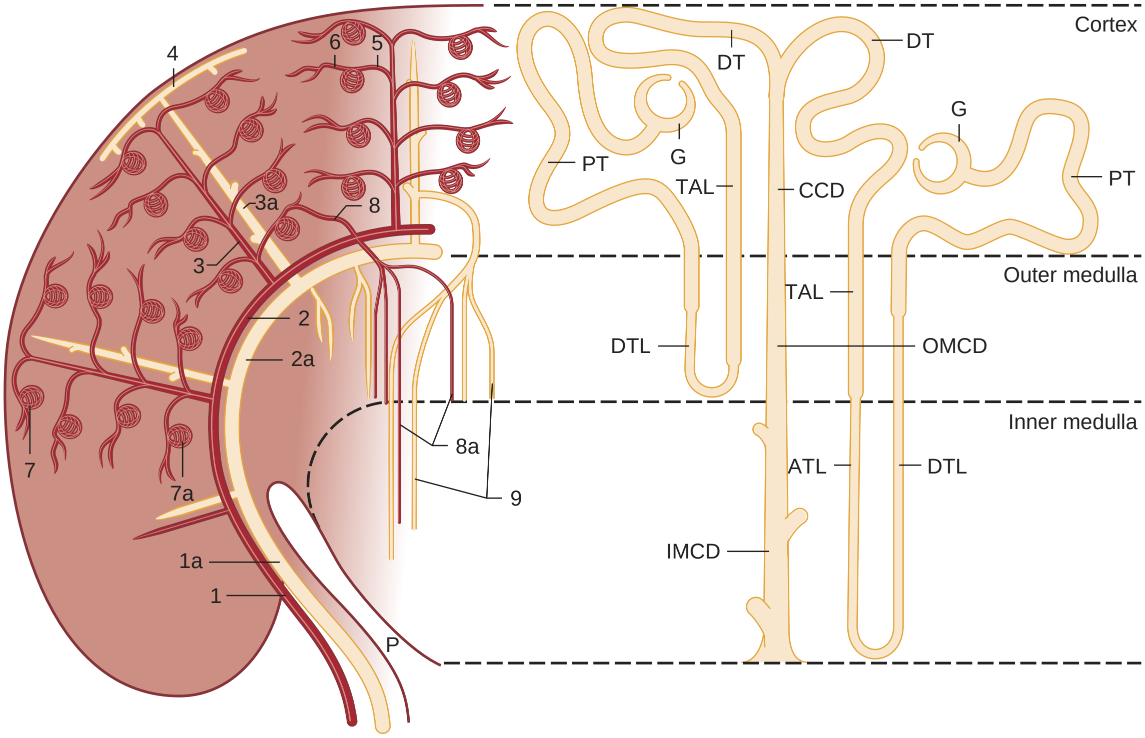

Fig. 17.1 Anatomic relationships of the nephron and the renal vasculature. The left side of the diagram represents the renal vasculature as distributed through the inner medulla, outer medulla, and cortex. Arteries are drawn as solid lines, veins as hollow tubes. The renal artery divides serially into interlobar arteries (1), arcuate arteries (2), and interlobular arteries (3). The afferent arterioles (5) branch off laterally and provide the capillary tufts of the renal glomeruli in the outer cortex (7a), whose efferent arterioles (6) supply the cortical capillary network (not shown). In the juxtamedullary zone (7b), the efferent arterioles become the vasa recta, which are closely applied to the long loops of Henle (8, 8a, 9). The venous drainage consists of stellate veins (4), interlobular veins (3a), arcuate veins (2a), and interlobar veins (1a). (Modified from Kriz W, Bankir L. A standard nomenclature for structures of the kidney. The Renal Commission of the International Union of Physiological Sciences (IUPS). *Kidney Int.* 1988;33[1]:1–7.)

epithelium that lines a pouch-like cistern, called Bowman space, which is the beginning of the renal tubular system.

The vasculature of the kidney is unique in that it has two capillary beds. Upon leaving the glomerulus, the glomerular capillary then forms the efferent artery that in turn leads to an anastomosing network of 10 to 25 long peritubular capillaries called vasa recta. The vasa recta are close around the ascending limb of the loop of Henle before anastomosis into veins that leave the kidney (see Fig. 17.2).

The endothelial and epithelial cells synthesize proteins that are essential components of the filtration barrier of the kidney, the GBM (see Fig. 17.5).[6] The GBM is rich in the anionic glycosaminoglycan heparin sulfate, Type IV collagen, and laminin.[6,7] The epithelial cells maintain the integrity of this capillary bed by producing several key molecules including vascular endothelial growth factor[8] and families of signaling proteins and receptors. The transmembrane protein nephrin supports the integrity of the slit pore diaphragms and its maintenance is dependent on the endocytosis of slit diaphragm proteins and plasma membrane components.[7,9,10] The interplay between the foot processes of the podocytes, slit diaphragms, and organization of the actin intracellular scaffolds is centered on nephrin and related proteins.[11] The functions of these numerous factors are often elucidated in experiential studies when found as etiologies of renal disease.[7,11]

THE RENAL TUBULES

The kidneys receive 20% of the total cardiac output but extract relatively little oxygen. The renal arteriovenous oxygen difference is only 1.5 mL/dL. However, there is marked dissimilarity between the renal cortex and medulla with regard to blood flow, oxygen delivery, and oxygen consumption (Table 17.1). The medulla receives only 6% of the

RBF and has an average oxygen tension (PO_2) of 8 mm Hg. Thus, severe hypoxia could develop in the medulla despite a relatively adequate total RBF; the metabolically active medullary thick ascending loop of Henle (mTAL) is particularly vulnerable.[12]

The terminology of the renal tubular system is based on morphology as seen with light microscopy. The system begins with the proximal convoluted tubule (PCT) that starts as a continuation of the parietal epithelium of the nephron (see Fig. 17.3). A high density of mitochondria and the extensive surface area of the apical (referred as the brush border) and basilar cell membranes mark the renal tubules and indicate high-energy requirements. In normal kidneys, 80% of the energy is required for Na^+/K^+-ATPase that maintains the osmotic gradient needed for the resorption of filtered molecules (Fig. 17.6).[2] In spite of this high-energy demand, the tubular system is supplied by only 10% to 15% of the RBF and is a key etiology for acute tubular necrosis after hypotension (see Chapter 42).

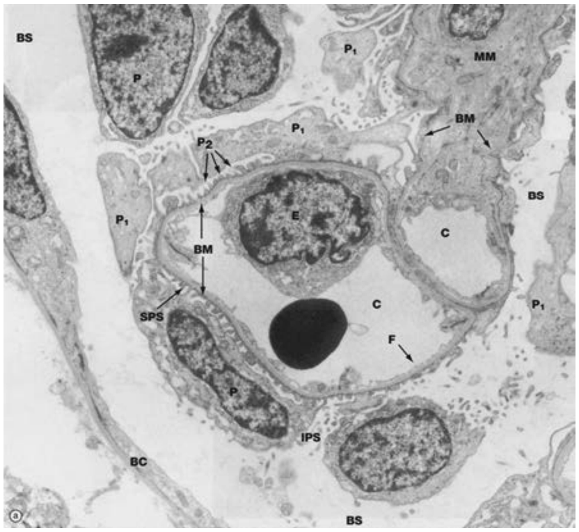

Fig. 17.4 Electron micrograph of glomerulus. The several glomerular capillaries *(C)* are lined by fenestrated endothelial cells. The podocytes *(P)* give rise to foot processes *(P_1, P_2)* that rest on the glomerular basement membrane *(BM)*. Mesangial cells *(M)* support the capillary loops. Bowman space *(BS)* is delineated by the podocyte bodies on one side and the parietal epithelial cells on the other. *E*, Nucleus of capillary; *IPS* interpodocyte space; *MM*, mesangial matrix; *SPS*, subpodocyte space. (From Young B, Woodford P, O'Dowd G. Urinary system. In: *Wheaton's Functional Histology. A Text and Colour Atlas.* 6th ed. Philadelphia: Elsevier Churchill Livingstone; 2014.)

A distal short straight length of the proximal tubule leads to the thinner epithelium of the descending thin limb of the loop of Henle. This makes a hairpin 180-degree turn to ascend toward the cortex and eventually becomes the medullary thick ascending limb of the loop of Henle (mTAL) and distal convoluted tube (see Fig. 17.2). Seventy to 80% of nephrons begin in the cortex and have short loops of Henle that enter only the outer margin of the medulla. The remaining juxtamedullary nephrons start at the corticomedullary junction and have elongated loops of Henle that descend into the most distal extent of the medulla. At the end of the distal tubule is the juxtaglomerular apparatus that is comprised of specialized epithelial cells, called the macula densa (by virtue of light microscopic image), cells of the afferent glomerular arteriole, and mesangial cells (Fig. 17.7). The juxtaglomerular apparatus is essential for the maintenance of blood pressure, as described later. The most distal end of the nephron is the collecting duct that empties the ultrafiltrate into the renal pelvis and then the ureters.

FORMATION OF URINE

Urine is formed by the interaction of three processes: glomerular filtration, tubular reabsorption, and tubular secretion.

Glomerular Filtration

The formation of the glomerular filtrate is dependent on the balance of Starling forces regulating fluid flux across the filtration barrier.[13] Central to this process is the pressure difference between the afferent and efferent arteries (Fig. 17.8). The hydrostatic pressure in the glomerular

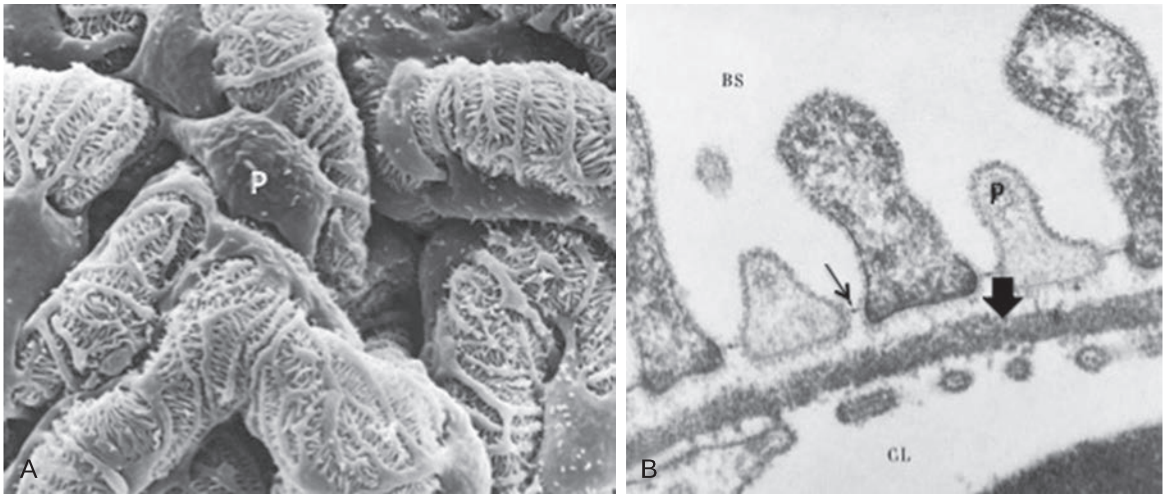

Fig. 17.5 (A) Scanning electron micrograph of podocytes *(P)* and their processes. (B) Electron micrograph of podocyte processes (P), the glomerular basement membrane, and glomerular capillaries. Slit diaphragms *(arrow)* span the podocyte processes. Large arrow points to the lamina densa of the glomerular basement membrane. *BS*, Bowman space; *CL*, glomerular capillary lumen. capillaries is 60 mm Hg, which is three times higher than in most capillary beds. This pressure difference drives plasma across the endothelial and epithelial filtration barriers (Table 17.2). A delicate balance in pressure maintenance is necessary because reduced pressures will decrease filtration, as increased pressures may cause renal damage. The glomerular filtration rate (GFR) depends upon the glomerular capillary pressure that is opposed by the hydrostatic pressure in Bowman space and the colloid osmotic pressure within the glomerular capillaries (Figs. 17.8 and 17.9). In healthy patients, the colloid osmotic pressure in Bowman

TABLE 17.1 Distribution of Renal Blood Flow Between Cortex and Medulla

*The renal medulla receives only a small fraction of the total renal blood flow, and flow rates are extremely slow. As a result, the tissue oxygen tension is extremely low, and the medulla extracts almost 80% of the oxygen delivered to it. A very mild reduction in total and cortical renal blood flow may therefore induce ischemia and hypoxia in the renal medulla. *DO_2*, Oxygen delivery; *O_2*, oxygen; *PO_2*, oxygen tension; *VO_2*, oxygen consumption. space is negligible, since the GBM restricts the passage of proteins. The normal GFR is about 180 L/day.

Mediator Control of the Glomerular Filtration Rate

Control of this glomerular capillary pressure is exquisite. Hormones, peptides, and autacoids interact with receptors in the kidney to assure maintenance of RBF and GFR (Fig. 17.10).

α-Adrenergic Effect. The vascular myocytes of afferent and efferent arterioles have the pressure-dependent ability to contract or relax. This prevents increased diuresis, appropriately called pressure diuresis, when the blood pressure is elevated. Mild α-adrenergic stimulation constricts the efferent arteriole that preserves GFR (Fig. 17.11). Severe α-adrenergic activity decreases the filtration fraction by constricting the afferent and efferent arterioles to prevent a flow-induced decrease in GFR. This is the reason norepinephrine administration during sepsis may preserve diuresis. This is important to understand during shock, when the endogenous adrenergic response or the use of α agonists may worsen renal hypoperfusion and decrease the GFR. The kidney is relatively devoid of β2 receptors, so epinephrine release induces predominant vasoconstriction through α receptor or angiotensin activation.

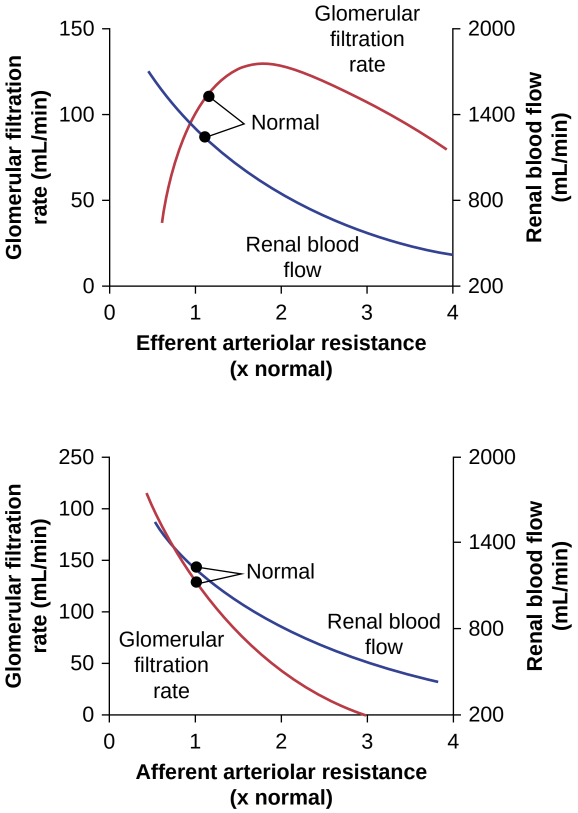

Fig. 17.11 Effect of change in afferent arteriolar resistance or efferent arteriolar resistance on glomerular filtration rate and renal blood flow. (Redrawn from Hall JE. *Guyton and Hall Textbook of Medical Physiology*. 13th ed. Philadelphia: Elsevier; 2016.)

Renin-Angiotensin. Adrenergic stimulation of the juxtaglomerular apparatus releases the enzyme renin from the cells of the macula densa and principal cells of the collecting ducts.[14] Renin, more appropriately called angiotensinogenase, converts the hepatic synthesized glycopeptide angiogensinogen to angiotensin I. Angiotensin-converting enzymes (ACEs) are present in diverse cell types,[12] including leukocytes and smooth muscle. The vascular endothelial cells of the kidney and lung are the major source of ACE that converts angiotensin I to angiotensin II.[12,15-17]

Angiotensin II stimulates two pathways that have opposing effects (Fig. 17.12). The principal receptor is AT_1 that is found on the luminal epithelial surface of the proximal tubular cell (PTC), mTAL, macula densa, distal tubules, and collecting ducts.[14,18] The angiotensin II-AT_1 interaction serves to maintain systemic blood pressure through vasoconstriction, and enhancement of tubular transport mechanisms to reabsorb sodium and water.[14,15,19] The binding of angiotensin II to "non-classical" receptors such as AT_7 opposes these actions and causes vasodilatation through nitric oxide (NO) and prostaglandin-mediated natriuresis, diuresis, and reduced oxidative stress.[19]

Angiotensin II is a potent vasoconstrictor of efferent arterioles, which increases the pressure difference and enhances filtration.[18] This maintains the glomerular filtration fraction in the face of mild to moderate decreases in RBF or perfusion pressure that may result from hypovolemia or systemic hypotension. Angiotensin II promotes systemic vasoconstriction at about one tenth of its renal effect. Renin secretion is stimulated by hypovolemia from hemorrhage, diuresis, or sodium loss/restriction and by reductions in perfusion as seen with positive pressure ventilation, congestive heart failure, sepsis, or cirrhosis with ascites. Angiotensin II feeds back to the juxtaglomerular apparatus to inhibit renin secretion. It also stimulates phospholipase A_2 to trigger the synthesis of vasodilatory prostaglandins.

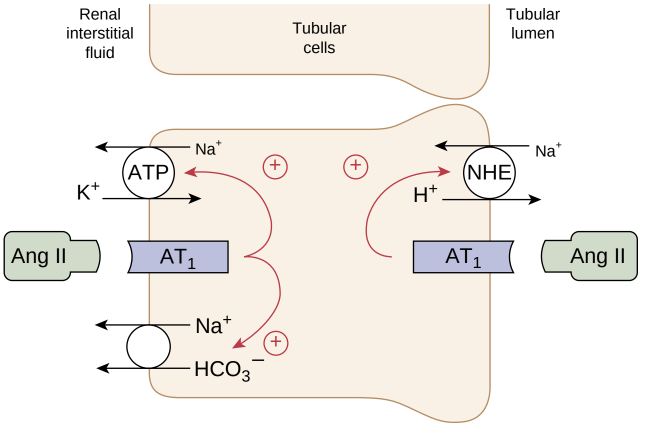

Fig. 17.12 Direct effects of angiotensin II *(Ang II)* to increase proximal tubular sodium reabsorption. Ang II stimulates sodium-hydrogen exchange *(NHE)* on the luminal membrane and the sodium-potassium ATPase transporter and sodium-bicarbonate co-transport on the basolateral membrane. *ATP*, Adenosine triphosphate. (Redrawn from Hall JE. *Guyton and Hall Textbook of Medical Physiology*. 13th ed. Philadelphia: Elsevier; 2016.)

Prostaglandins and Kinins. Intrarenal prostaglandins play an important role in endogenous renal protection by vasodilating juxtamedullary blood vessels and maintaining inner cortical blood flow.[20] Prostaglandins are called autacoids because, unlike true hormones, they are produced in minute amounts and have a local, evanescent action. Because their structure is based on a 20-carbon fatty acid, they are also referred to as eicosanoids, after *eicosa*, the Greek word for the number 20.

Phospholipase A_2 resides in the inner lipid layer of the cell membrane and controls prostaglandin production through its formation of the prime precursor, arachidonic acid. It is stimulated by ischemia, hypotension, norepinephrine, angiotensin II, and arginine vasopressin (AVP). Thus, the factors that induce and mediate the stress response simultaneously activate prostaglandins, which defend the kidney against their actions. Cyclooxygenase-1 acts on arachidonic acid to form the vasodilator prostaglandins that include PGD2, PGE2, and PGI2 (prostacyclin).[21] Vasodilation is through activation of cyclic adenosine monophosphate (cAMP) to oppose the action of catecholamines, angiotensin II, and AVP. Prostaglandins may be particularly important in decreasing the vasoconstrictor activity of angiotensin II on the afferent arteriole and mesangial cells. Drugs that inhibit prostaglandin synthesis, such as nonsteroidal anti-inflammatory agents, can upset this compensatory mechanism and result in medullary ischemia.

Kinins act directly as vasodilators, as well as stimulate phospholipase A_2, prostacyclin production, and endothelial cell NO formation.[22] Kinins are produced by cleavage of kininogen by the serine protease kallikrein. Over 90% of renal kallikrein is produced by the distal convoluted tubules

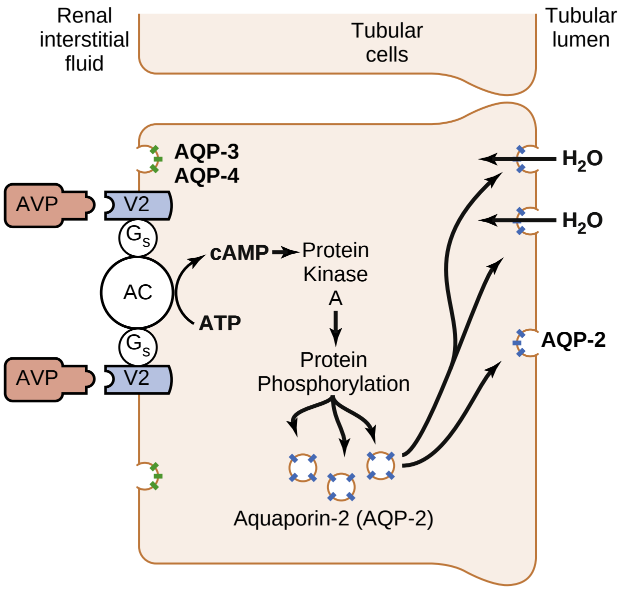

Fig. 17.13 Mechanism of action of arginine vasopressin. Arginine vasopressin *(AVP)* binds to receptors *(V_2)* that are coupled to G proteins *(G_s)* to activate adenylate cyclase *(AC)* and stimulate the formation of cyclic adenosine monophosphate *(cAMP)*. This will then activate protein kinase A to phosphorylate intracellular proteins and allow aquaporin-2 *(AQP-2)* to form water channels at the luminal side of the membrane. Other aquaporins *(AQP-3, AQP-4)* that are not controlled by AVP allow water to exit the cell at the basolateral cell membrane. *ATP*, Adenosine triphosphate. (Redrawn from Hall JE. *Guyton and Hall Textbook of Medical Physiology*. 13th ed. Philadelphia: Elsevier; 2016.)

in the cortex with decreased concentrations from outer to inner zones.[22] Renal kininase, which controls the level of bradykinin, is inhibited by ACE inhibitors and is the reason for angioedema.[23]

Arginine Vasopressin. AVP, also known as antidiuretic hormone (ADH), is produced by the posterior pituitary, and its release is stimulated by hyperosmolality or hypovolemia.[24] By far the most potent trigger for AVP release is systemic arterial hypotension, mediated by aortic and carotid baroreceptors. It overrides all other triggers, and plasma AVP may reach levels 10- to 1000-fold greater than normal. At these concentrations, AVP acts as a vasoconstrictor, especially in the outer renal cortex. It does so by stimulating the V_{1A} receptor that exists on vascular smooth muscle, glomerular mesangial cells, and the vasa recta and promotes vasoconstriction through the phosphatidylinositol pathway.[25] AVP maintains effective glomerular filtration pressure because it is an extremely potent constrictor of the efferent arteriole, and unlike catecholamines and angiotensin, it has little effect on the afferent arteriole, even at high plasma levels.[26] The binding to V_2 receptors on the medullary collecting ducts stimulates adenylate cyclase to form cAMP that enhances aquaporin-2 channels of the principal cells to increase water reabsorption (Fig. 17.13).[24,27] Anesthetics have little direct effect on AVP secretion, except via the changes that they induce in arterial blood pressure, venous volume, and serum osmolality. Surgical stimulation is a major stimulus to AVP secretion. This stress response, whether mediated by pain or by intravascular volume changes, is profound and lasts at least 2 to 3 days after the surgical procedure.

Natriuretic Peptides. Natriuretic peptides dilate vascular smooth muscle through activation of cyclic guanosine monophosphate by blocking the phospholipase C-linked receptors to the actions of norepinephrine and angiotensin II. Atrial natriuretic peptide (ANP)[28] is released from atrial myocytes in response to atrial wall stretch and increased atrial volume, brain (B-type) natriuretic peptide is released in response to cerebral ventricle stretch, and C-type is released from the endothelium of major blood vessels. Urodilatin is secreted by the epithelium of the distal tubules and collecting ducts in response to increases in mean arterial pressure and blood volume.

The natriuretic peptides cause prompt, sustained increases in GFR and glomerular filtration fractions even when RBF is not increased or when arterial pressure is decreased. They promote afferent arteriolar dilatation with or without efferent arteriolar constriction, antagonize endothelin (the endogenous vasoconstrictor peptide produced by vascular endothelial cells), inhibit renin secretion, and decrease angiotensin-stimulated aldosterone. These peptides also inhibit the release of aldosterone in the adrenal cortex and block its actions at the distal tubules and collecting ducts. Moreover, they inhibit the secretion of AVP through their effects on the brain and pituitary, which can lead to an enhanced diuresis. NaCl is resorbed, and diuresis is promoted.[29] These actions are important in oliguric patients (such as those with acute renal failure and chronic renal failure) to increase urine output.

Aldosterone. Aldosterone is a steroid hormone secreted by the zona glomerulosa of the adrenal cortex in response to hyperkalemia or hyponatremia.[30] Angiotensin II and adrenocorticotropic hormone also trigger its release. It acts at the thick ascending limb of the loop of Henle, the principal cells of the distal tubule, and the collecting duct to increase active absorption of sodium and passive absorption of water, culminating in an expanded blood volume. Sodium retention in vessel walls appears to enhance their response to vasoconstrictor agents. In contrast to the immediate sympathetic angiotensin II response to hypovolemia, there is a delay of about 1 to 2 hours from the secretion of aldosterone to its action on sodium reabsorption.

Aldosterone forms a complex with a receptor at the cell membrane in the principal cells of the distal tubule (Fig. 17.14). The aldosterone-receptor complex travels to the cell nucleus, where it induces cytoplasmic transcription of messenger ribonucleic acid. This fosters synthesis of proteins that form sodium channels in the apical cell membrane and enhance the $Na^+/K^+/ATPase$ pump in the basolateral cell membrane.[31] Sodium is transported from the tubular fluid into the peritubular capillary in exchange for potassium. Long-standing stimulation of aldosterone secretion, characteristically induced by the intravascular volume depletion of chronic ascites, culminates in potassium depletion and hypokalemic alkalosis.

The Dopaminergic System

There are at least two subtypes of dopaminergic (DA) receptors.[32] DA1 receptors are present on the renal and splanchnic vasculature and also on the proximal tubule. Stimulation of the DA1 receptor activates cAMP and induces renal vasodilation, increased RBF and GFR, natriuresis, and diuresis. Dopamine inhibits the sodium-hydrogen antiporter system

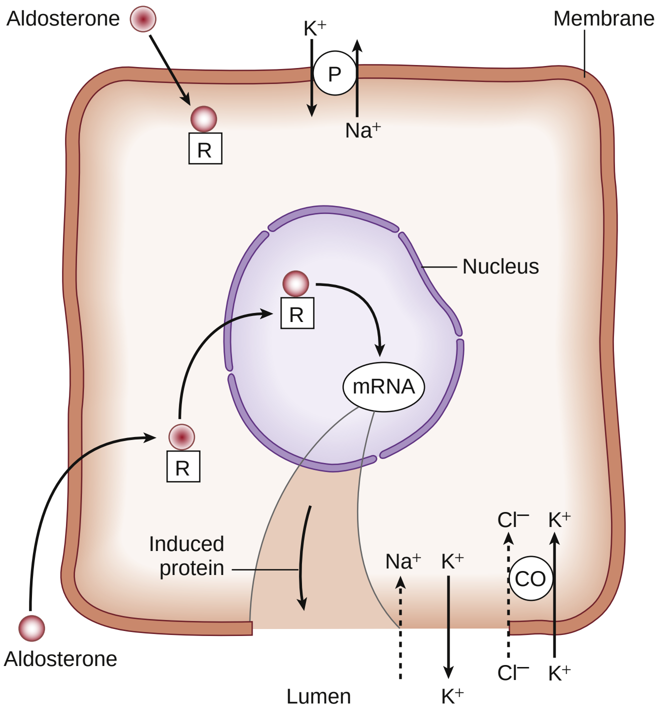

Fig. 17.14 Action of aldosterone. Aldosterone enters the distal tubular cytoplasm and attaches to a receptor, then migrates to the nucleus, where it induces the formation of messenger ribonucleic acid *(mRNA)*. The mRNA in turn induces the synthesis of a protein that enhances the permeability of the apical (luminal) membrane to sodium and potassium. The reabsorption of sodium stimulates the basolateral membrane Na-K-ATPase pump, the intracellular concentration of potassium rises, and it follows its concentration gradient out into the lumen. The net effect of aldosterone's action is sodium reabsorption and potassium loss. Cl^-, Chloride; *CO,* cotransporter (= symporter); K^+, potassium; Na^+, sodium; *P,* sodium-potassium ATPase pump; *R,* receptor. (From Wingard LB, Brody TM, Larner J, et al. Diuretics: drugs that increase excretion of water and electrolytes. In: Wingard LB, Brody TM, Larner J, et al., eds. *Human Pharmacology: Molecular-To-Clinical.* London: Wolfe Publishing Ltd; 1991:249, Fig. 19.4.)

at the brush-border membrane of the proximal tubule and the Na^+/K^+/ATPase pump at the basolateral membrane of the thick ascending limb of the loop of Henle to enhance NaCl reabsorption.

Stimulation of D2 receptors on the presynaptic terminal of postganglionic sympathetic nerves inhibits the release of norepinephrine from presynaptic vesicles to facilitate vasodilation. The DA system plays an integral role in the endogenous vasodilator-natriuresis system and the maintenance of normal blood pressure. Endogenous dopamine constitutively activates the DA2 receptor, which synergistically enhances the activation of the DA1 receptor and inhibits tubular Na^+/K^+-ATPase activity, especially when sodium intake is increased. It also opposes the anti-natriuretic effects of norepinephrine, angiotensin II, and aldosterone. Endogenous ANP acts via the renal dopamine system by recruiting "silent" DA1 receptors from the interior of the cell toward the plasma membrane and also enhances dopamine accumulation.[32,33]

Urinary dopamine excretion is increased with salt loading; decreased DA activity may contribute to the pathogenesis of idiopathic edema, which manifests as retention of salt and water in the upright position. There is evidence that the endogenous dopamine system is activated in compensated cirrhosis and helps to maintain renal sodium excretion.[32,33]

Adenosine

Adenosine is present in all tissues and in the extracellular space as a signaling molecule. It plays a role during conditions of cellular distress such as hypoxia, inflammation, and acute cellular injury.[34] Extracellular adenosine mainly exerts its biologic actions through activation of four adenosine receptors that lead to the attenuation or activation of intracellular cAMP levels through modulation of adenylate cyclase activity. This modulation of cAMP affects the production of nucleotides adenosine monophosphate, adenosine diphosphate (ADP), and adenosine triphosphate (ATP) that have essential roles in most cellular functions.[34] Adenosine is implicated in the regulation of RBF by tubuloglomerular feedback and protects the kidney from ischemia.[35] During periods of ischemia, there is a fivefold increase in extracellular adenosine. In animal models, receptors for adenosine have been effective in preventing or treating acute kidney injury (AKI) from ischemia.[35]

Nitric Oxide

Endogenous NO is a potent vasodilator of vascular smooth muscle. It is produced in many nephron segments including the cortical and medullary thick ascending limb of the loop of Henle (mTAL).[36] During oxidative stress, reactive oxygen species (ROS), including superoxide (O_2^-), hydrogen peroxide (H_2O_2), and the hydroxyl radical (OH), are produced. Under normal conditions, NO minimizes the influence of these ROS. NO acts at multiple points in the citric acid cycle and increases the efficiency of oxygen utilization within the kidney.[36] NO inhibits apical Na^+/H^+ cotransport and basolateral Na^+/K^+-ATPase activity in the proximal tubule, inhibits sodium reabsorption in the mTAL by blocking the $Na^+/K^+/2Cl^-$ cotransporter, and has a direct effect on apical sodium channels of the cortical collecting ducts to inhibit sodium transport.[36,37] NO produced in the epithelial cells of mTAL buffers the vasoconstriction in the medullary circulation in response to sympathetic stimulation and angiotensin II.[38] As for antagonism of O_2^- tubular activity, endogenous NO counteracts the vasoconstrictor effects of O_2^-.

Renal Tubular System Physiology

The renal tubular system compensates for the large glomerular filtration by resorption so that only 1.5 L/day of fluid is excreted as urine. The tubules also conserve and regulate molecules within appropriate physiologic ranges that are freely filtered such as ions, glucose, and amino acids (Table 17.3). Under most conditions, the kidneys excrete more than 95% of the ingested Na^+ at rates that match dietary Na^+ intake.[39] Approximately 65% of filtered sodium, chloride, and water is reabsorbed by the PCTs (Fig. 17.15). In the first segment of the PCT, sodium moves across the apical lumen by cotransport with amino acids, bicarbonate, and glucose and counter-transport mechanisms (Fig. 17.16). This reabsorption increases the concentration of chloride ions to 140 mEq/L from the initial filtrate concentration of 105 mEq/L and favors its diffusion through the intercellular junctions into the interstitial space. Organic acids and bases including waste products of metabolism, such as bile salts and urea, and multiple exogenous molecules are cleared by the PCT. This clearance has additional clinical importance since doses of drugs that are removed by the kidney, such as β-lactam antibiotics, will require dose

Fig. 17.15 Summary of major activities of different parts of the renal tubule. The ability of the tubule to produce concentrated urine is dependent on the high osmolality of the renal medulla created by the counter-current multiplier mechanism. This is dependent upon the active transport of NaCl in the water-impermeable thick ascending limb of the loop of Henle NaCl, the action of arginine vasopressin (antidiuretic hormone, *ADH*) on the collecting tubule and duct, the high concentration of urea created by passive diffusion, and the reabsorption of water reabsorbed into the hyperosmolar medulla by the vasa recta. (Redrawn from Young B, Woodford P, O'Dowd G. Urinary system. *Wheaton's Functional Histology. A Text and Colour Atlas*. 6th ed. Philadelphia: Elsevier Churchill Livingstone; 2014.)

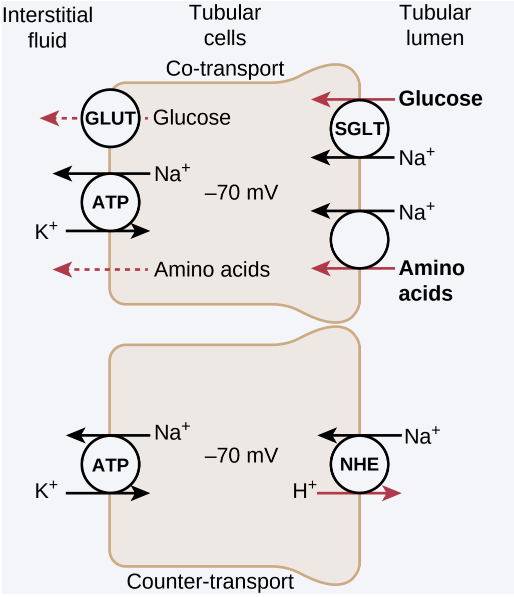

Fig. 17.16 Mechanism of secondary active transport. The upper cell shows the cotransport of glucose and amino acids along with Na^+ through the apical side of the tubular epithelial cells followed by facilitated diffusion through the basolateral membranes. The lower cell shows the counter-transport of hydrogen ions from the interior of the cell across the apical membrane and into the tubular lumen. The movement of sodium ions into the cell is down an electrochemical gradient established by the sodium-potassium pump at the basolateral membrane and provides the energy for transport of the hydrogen ions from the inside of the cell into the tubular lumen. *ATP*, Adenosine triphosphate; *GLUT*, glucose transporter; *NHE*, sodium hydrogen exchanger; *SGLT*, sodium-glucose co-transporter. adjustments to achieve therapeutic levels or to prevent toxicity in other organs. Fig. 17.17 outlines changes in the concentrations of different substances in the tubular system relative to the concentration in plasma and the glomerular filtrate.

The Loop of Henle

The loop of Henle is comprised of a thin descending limb, thin ascending limb, a medullary thick ascending limb (mTAL) as well as a cortical portion that leads to the distal convoluted tubule. The macula densa (see Fig. 17.1) is an area of closely packed cells lining the wall of the distal tubule at the point where it meets the thick ascending limb.The major function of the loop of Henle is the maintenance of an osmotic gradient in the interstitium by a countercurrent system to allow the resorption of 40% of the filtered sodium and 25% of filtered water (see later).[39] Differential permeability to water, transport of ions, and urea carriers provide the interstitial environment to concentrate urine (see Fig. 17.15). The tubules of the descending loop of Henle are freely permeable to water and allow for the reabsorption of about 20% of the filtered water. Both the medullary and cortical thick limbs are impermeable to water and function to concentrate urine. Urea, which comprises 90% of waste nitrogen, is passively absorbed in the tubules by osmosis and is facilitated by specific transporters. An increased concentration of urea in the tubular lumen favors its movement into the interstitium to create an extremely high interstitial osmolality at the tip that approaches 1200 mOsm/kg. Since the tubules are less permeable to urea than water, most of the urea is excreted into the urine.

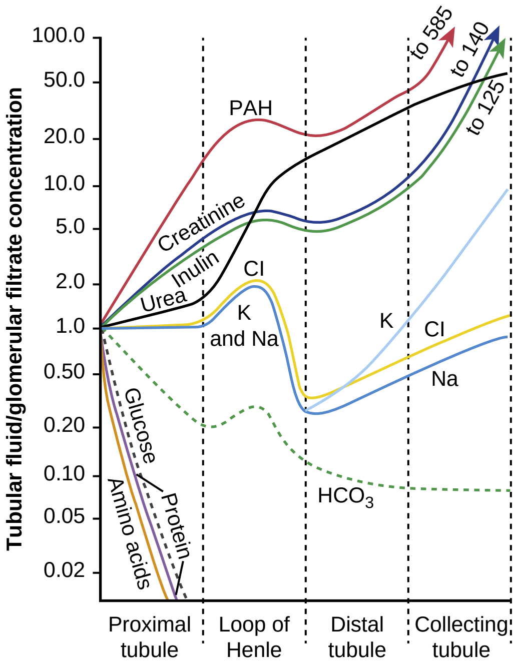

Fig. 17.17 Changes in the average concentrations of different substances at different points in the tubular system relative to the concentration of that substance in the plasma and in the glomerular filtrate. A value of 1.0 indicates that the concentration in the tubular fluid is the same as in the plasma, values below 1.0 indicate that the substance is reabsorbed more avidly than water, while values greater than 1.0 indicate that the substance is reabsorbed to a lesser extent than water or is secreted into the tubules. (Redrawn from Hall JE. *Guyton and Hall Textbook of Medical Physiology*. 13th ed. Philadelphia: Elsevier; 2016.)

As with the cells of the PCT, the mTAL cells have high metabolic activity. A $Na^+/K^+/2Cl^-$ cotransporter in this segment absorbs Na^+, Cl^-, and K^+ from the tubular lumen. Inhibition of this cotransporter is the mechanism of cationic (positively charged) loop diuretics such as furosemide. The positive charge of the tubular lumen compared to the interstitium allows the paracellular reabsorption of magnesium and calcium in addition to sodium and potassium. ATPase-dependent Na^+/K^+ pumps in the basilar membrane will reabsorb 25% of the filtered sodium and potassium.

DISTAL TUBULES AND MACULA DENSA

The first part of the distal tubule forms the macula densa of the juxtaglomerular apparatus. Approximately 5% of sodium is reabsorbed in the first part of the distal tubule by a sodium chloride cotransporter that moves ions from the tubular lumen into the cell and a Na^+/K^+ ATPase that moves Na^+ out of the cell.[39,40] Thiazide diuretics inhibit this cotransporter (see Fig. 17.16). The movement of chloride is passive. The permeability to water of the distal tubules, as well as the collecting tubules described later, is regulated by AVP (Fig. 17.18). With increased AVP, the tubules become more permeable and water is absorbed.

COLLECTING TUBULES

The collecting tubules are extensions of the distal tubules and have the same function of Na^+ resorption. The two cell types lining the collecting tubules are the principal

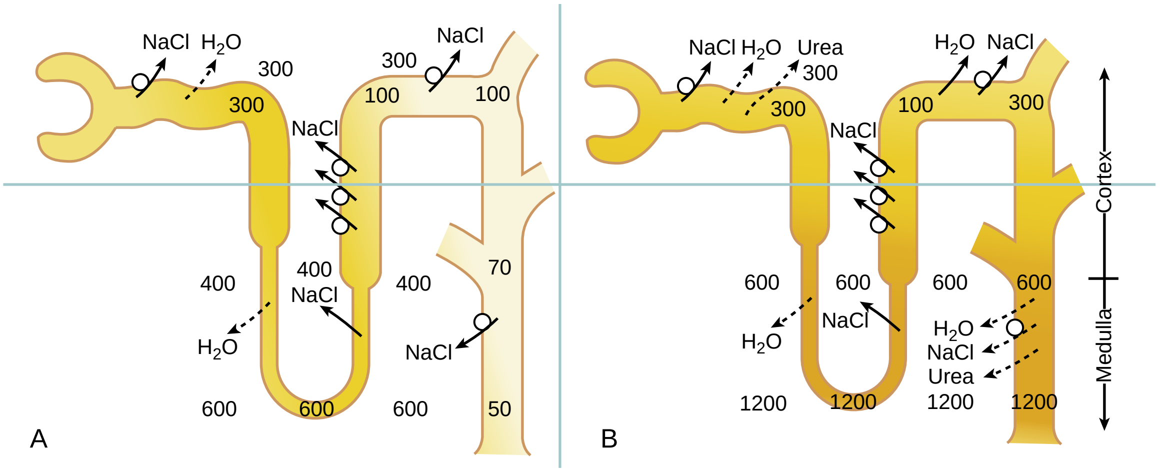

Fig. 17.18 Effect of arginine vasopressin on the formation of urine. (A) With low levels of arginine vasopressin (AVP), fluid in the ascending limb of the loop of Henle is dilute and becomes further diluted in the distal and collecting tubules by continued reabsorption of solutes (indicated as millimoles per liter) while water is not resorbed. (B) Urine is concentrated when AVP is high. Fluid leaving the loop of Henle becomes more concentrated as water is absorbed from the distal and collecting tubules. With high AVP levels, the osmolality of the urine (indicated as milliosmoles) is the same as in the renal medullary interstitial fluid. (Modified from Hall JE. *Guyton and Hall Textbook of Medical Physiology*. 13th ed. Philadelphia: Elsevier; 2016.)

cells and two types of intercalated cells. Principal cells use Na^+/K^+ ATPase to resorb Na^+ and K^+. These cells are the sites of action for the potassium-sparing diuretics such as spironolactone, a competitor of aldosterone. An additional mechanism is Na^+ channel blockade by diuretics such as amiloride.

Type A intercalated cells use H^+-ATPase and H^+/K^+-ATPase transporters to secrete hydrogen ions formed by carbonic anhydrase against a large concentration gradient. Bicarbonate ions are absorbed from the basolateral membrane. In contrast, the Type B intercalated cells transport hydrogen out of the cell on the basolateral side while bicarbonate is excreted into the tubular lumen. These cells are critical to the maintenance of acid-base balance, sodium reabsorption, and intravascular volume.[41]

COLLECTING DUCTS

The collecting ducts form as distal anastomoses of collecting tubules in the medulla and determine the final composition of urine. The principal cell of the collecting duct is a highly regulated epithelial cell. AVP controls water resorption. Urea is reabsorbed via transporters into the medullary interstitium, thereby raising the osmolality to assist in the concentration of urine. Hydrogen can also be secreted against a high concentration gradient to regulate acidosis.

RENAL AUTOREGULATION

The formation of urine is tightly controlled by complex autoregulation that maintains consistency of the RBF, GFR, and the resorption rate in tubules when there are changes in tubular flow. This autoregulation protects the kidney from injury secondary to elevated blood pressure by two mechanisms: autoregulation of RBF and tubuloglomerular feedback.[42]

Autoregulation of Renal Blood Flow

The smooth muscles of the afferent arterioles, as in other vascular beds, have the intrinsic ability to contract, called a myogenic response, to increases in blood pressure. The response can compensate for changes in pressure within 3 to 10 seconds over a mean arterial blood pressure range of 70 to 130 mm Hg.[43]

The Myogenic Mechanism of the Renal Blood Flow Autoregulation

Glomerulotubular balance compensates for increased GFR when blood pressure is elevated by preventing fluid loss through an augmented rate of tubular absorption in the PTC and loop of Henle. This process is more adaptable to slow changes in arterial pressure (>20 seconds) and more critical in maintaining GFR and RBF during sustained reductions in blood pressure (Fig. 17.19).[43] An increase in GFR provides enhanced NaCl delivery to the distal tubules. The increased chloride concentration is sensed by the macula densa and triggers the renin-angiotensin cascade to decrease the GFR through angiotensin II constriction of the afferent arteriole. This trigger is sent by the macula densa through the complex of mesangial cells to the smooth muscle of the vasculature by paracrine signaling. There are no intercellular connections between the macula densa, other components of the juxtaglomerular apparatus, and the blood vessels.[44] The increases in resorption proportionate to the GFR prevent distention of the distal tubular segments.

TUBULOGLOMERULAR FEEDBACK

The dynamic range of tubuloglomerular feedback is a NaCl concentration between 15 and 60 mmol/L with maximal responses at greater than 60 mmol/L.[44] In the tubules, more than 99% of water and most of the solutes are absorbed, pass through the interstitium, and enter the capillaries at a rate of 124 mL/min. As demonstrable for most capillary beds, the transit of fluids is dependent upon balance of hydrostatic and colloid forces (see Fig. 17.8). Intravascular pressure (13 mm Hg) and colloid osmotic pressure of the interstitium (15 mm Hg) oppose resorption, whereas the hydrostatic pressure in the interstitium (6 mm Hg), intravascular colloid osmotic pressure (32 mm Hg), and large surface area of the capillaries favor resorption.

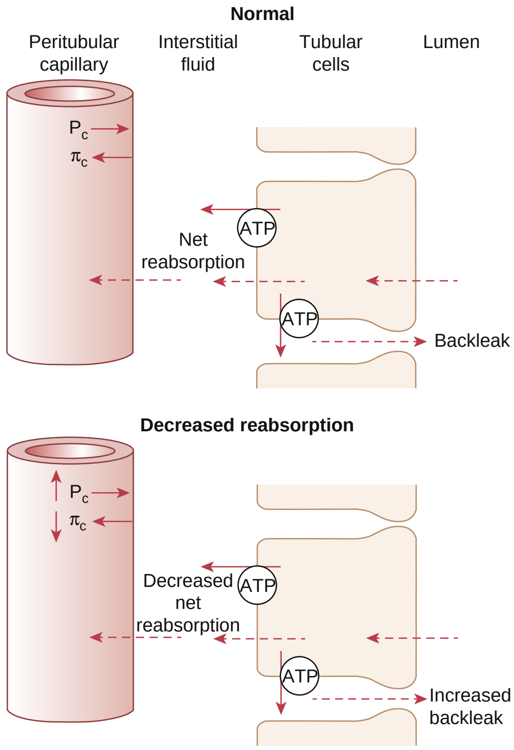

Fig. 17.19 Proximal and peritubular capillary reabsorption under normal conditions *(top)* and during decreased peritubular capillary reabsorption caused by increased hydrostatic pressure *(P_c)* or decreased colloid osmotic pressure *(π_c)*. As peritubular capillary reabsorption decreases, the net reabsorption of solutes and water is lowered by the increase in solutes and water that leak back into the tubular lumen through the tight junctions of the tubular epithelial cells. *ATP*, Adenosine triphosphate. MAINTENANCE OF PLASMA OSMOLALITY

Definition

Prior to any description of this process, the definitions of osmolarity and osmolality should be reviewed. Osmolality is a measure of the osmoles (Osm) of solute per kilogram of solvent (Osm/kg) while osmolarity is defined as the number of osmoles of solute per liter of solution (Osm/L). Osmolarity is affected by changes in water content, temperature, and pressure. Osmolarity is slightly less than osmolality because the total solvent weight excludes any solutes. Clinically, the values for osmolarity and osmolality are very similar, and the terms are usually used interchangeably. The bedside calculation from laboratory data (2[Na^+ mmol/L] + 2[K^+ mmol/L] + BUN mg/dL/2.8 + glucose mg/dL/18) is in units of osmolarity. The clinical laboratory measurements determined with osmometers are reported as osmolality.

Regulation of Osmolality

Plasma osmolality is closely regulated between 275 and 300 mOsm/L. Acute alterations in osmolality, either hypoosmolality or hyperosmolality, can result in serious neurologic symptoms and death as the result of water movement in the brain. Normal patients can dilute and concentrate urine within the range of 40 to 1400 mOsm/L.[45] Maintenance of plasma osmolality is linked to the regulation of sodium concentration and water balance by the tubular system and the collecting ducts in concert with the vasa recta blood supply of the tubules through differences in tubular permeability to water and the control of sodium transport (Fig. 17.20). It is dependent on the interaction of at least three processes: the generation of a hypertonic medullary interstitium by the countercurrent mechanism and urea recycling, the concentration and then dilution of tubular fluid in the loop of Henle, and the action of AVP to increase water permeability in the last part of the distal tubule and collecting ducts.

ROLE OF PROXIMAL TUBULES AND LOOP OF HENLE

Osmosis, the spontaneous net movement of solvent molecules through a selectively permeable membrane into a region of higher solute concentration to equalize the solute concentrations on the two sides, takes place in the proximal tubule. Proximal tubule solutes and water are equally reabsorbed so that the fluid in the tubules is isosmotic with plasma. In contrast, the organization of the loop of Henle is designed to maintain hyperosmolality of the medullary interstitium that can approach 1200 mOsm/L. The major process for this is the active transport of Na^+ and co-transport of K^+ and Cl^- from the lumen of the thick limb of the loop of Henle that is impermeable to water to the interstitium. This allows for a concentration gradient of 200 mOsm/L.

Medullary Interstitium

The medullary interstitium becomes hypertonic by the countercurrent multiplier effect of the loop of Henle that is best understood diagrammatically (Fig. 17.21). The primary mechanism is by the combination of NaCl reabsorption and water impermeability in the ascending limb. The descending limb is freely permeable to water, which diffuses into the interstitium along the osmotic gradient, and the tubular fluid becomes progressively hyperosmotic at the bend of the loop.

Water entering the distal convoluted tubule after leaving the loop of Henle is dilute (about 100 mOsm/L).

Fig. 17.22 Countercurrent exchange in the vasa recta. Plasma flowing down the descending limb of the loop of the vasa recta becomes more hyperosmotic (in millimoles per liter) as water diffuses out of the blood while solutes from the interstitial fluid flow into the blood. In the ascending limb, solutes diffuse back to the interstitial fluid and water diffuses back into the vasa recta. (Redrawn from Hall JE. *Guyton and Hall Textbook of Medical Physiology*. 13th ed. Philadelphia: Elsevier; 2016.)

This dilution is increased because of the active transport of NaCl and the impermeability of the epithelium. In the collecting tubule, resorption of water is dependent upon the action of AVP (ADH), since the epithelium is normally impermeable to water. With the action of AVP, large amounts of water are reabsorbed into the interstitium of the cortex and removed by the peritubular capillaries (see Fig. 17.18).

Vasa Recta

The vasa recta or straight arterioles of kidney are a series of straight capillaries that lie parallel to the loops of Henle of the juxtamedullary nephrons (Fig. 17.22). Only 5% of the RBF is through the vasa recta, creating a sluggish flow. As the capillaries descend into the medulla, the blood becomes more concentrated by solute entry from the interstitium. This high concentration in the ascending vasa recta in turn facilitates the entry of water from the ascending tubules. The combined interactions of tubular permeability and the vasa recta create the standing osmotic gradients in the cortex (300 mOsm/L), juxtamedullary zone (600 mOsm/L), and deep medulla (1200 mOsm/L).

The Role of Urea

A healthy person excretes 20% to 50% of the filtered load of urea. The concentration of urea entering the tubular system is related to the prerenal plasma concentration and the GFR. Urea contributes 40% to 50% of the osmolality of the medullary interstitium. The PCT are freely permeable whereas the loop of Henle, distal tubules, and the collecting ducts have little permeability to urea (Fig. 17.23). As water absorption increases with AVP action, the concentration of urea in the tubules progressively increases. With this high concentration, urea diffuses into the interstitial fluid facilitated by specific urea transporters that are activated by AVP. The simultaneous movement of urea and water out of the inner medullary collecting ducts maintains a high concentration of urea in the tubular fluid. As the concentration of urea increases in the medullary interstitium, it diffuses through the thin limb of the loop of Henle and transits through the ascending system again before it is excreted. This recirculation enhances the increased osmotic pressure in the medulla.

RENAL CONTROL OF INTRAVASCULAR VOLUME

Hypovolemia

Patients with hypovolemia, for example, from hemorrhage, gastrointestinal loss, or preoperative fasting, are commonly encountered in the perioperative period. Contraction of the extracellular volume by hypovolemia increases sympathetic outflow, activates the renin-angiotensin-aldosterone response, and releases AVP. Initially, the GFR and filtered load of sodium decrease. Sodium reabsorption in the proximal tubule is increased from about 66% to 80%

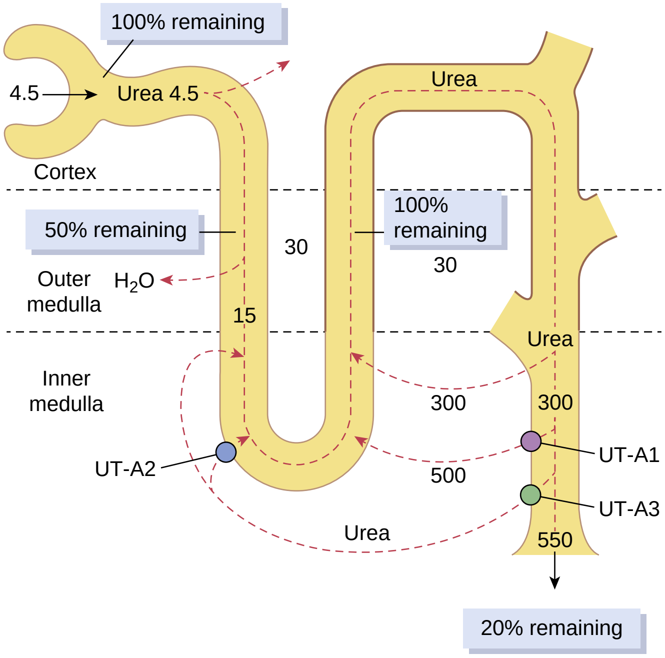

Fig. 17.23 Recirculation of urea absorbed from the medullary collecting duct into the interstitial fluid. Urea diffuses into the thin loop of Henle assisted by urea transporter UT-A2 through to the distal tubules and finally passes back to the collecting duct aided by urea transporters (*UT-A1* and *UT-A3*). This recirculation helps to trap urea in the renal medulla contributing to its hyperosmolality (millimoles per liter). Heavy lines indicate segments that are not very permeable to urea. (Redrawn from Hall JE. *Guyton and Hall Textbook of Medical Physiology*. 13th ed. Philadelphia: Elsevier; 2016.)

by sympathetic activity and angiotensin II, as well as by the decline in peritubular capillary pressure induced by renal vasoconstriction. Sodium delivery to the thick ascending loop of Henle, distal tubule, and collecting duct is decreased, but aldosterone promotes reabsorption of sodium at these sites. Under the influence of AVP, water is also avidly reabsorbed in the collecting duct so that the urine becomes highly concentrated (osmolality 600 mOsm/kg) but with virtually no sodium (10 mEq/L).

Hypervolemia

Expansion of the extracellular volume by hypervolemia is countered by an increase in the GFR and filtered sodium load due to a combination of reflex decreases in sympathetic and angiotensin II activity and the release of ANP. Together with the increase in peritubular capillary hydrostatic pressure, these responses cause sodium reabsorption in the proximal tubule to decrease from 67% to 50%. The decline in plasma aldosterone decreases sodium absorption from the thick ascending loop of Henle to the collecting duct. The presence of ANP and absence of AVP impairs water absorption at the collecting duct so that a dilute urine (osmolality 300 mOsm/kg) with abundant sodium (80 mEq/L) is produced.

CLINICAL TESTS FOR RENAL FUNCTION[46,47]

Urine Output

The measurement of urine output is simple and has been the traditional intraoperative and postoperative clinical evaluation of renal function in the absence of laboratory data. By consensus, oliguria is defined as a urine flow rate less than 0.5 mL/kg/h; it is often interpreted as a sign of renal dysfunction[48] and was first described by Galen and Ephesus between 100 and 200 AD. Urine output was listed as one of the most widely used indicators for volume expansion with intravenous fluids by 77% to 83% of anesthesiologists surveyed and based on a survey of United States and European anesthesiologists.[49] However, studies have shown that low urine output was not necessarily associated with renal failure.[50] Reduced intraoperative urinary output (<1 mL/kg/h) for patients undergoing anesthesia for thoracic resections was not associated with postoperative renal dysfunction regardless of the amount of fluid administered.[51] Although traditionally oliguria is taken as a sign of hypovolemia and subsequent reduction in kidney perfusion, perioperative oliguria is not always abnormal, especially when no other signs of hypoperfusion are present. Tolerance of modest oliguria is necessary when considering the relatively recent push for fluid limitations with enhanced recovery after surgery protocols.[52] Targeting urine output does not affect 30-day mortality, and oliguria is not a modifiable risk factor for mortality.[53] Oliguria has been correlated with AKI and may be a better threshold for the guidance of fluid administration.[54]

In the perioperative period, transient oliguria is almost inevitable, whether induced by hypotension, as an appropriate prerenal response to intravascular hypovolemia, or as a manifestation of the physiologic response to surgical stress.[55] It is a relative condition that depends on *expected* urine flow, and it may bear little, if any, relationship to GFR. When arterial blood pressure and intravascular volume are restored to normal levels, normal urinary flow should resume. Complete, often abrupt, cessation of urine flow (anuria) suggests postrenal obstruction. For patients with indwelling urinary catheters, obstruction of the catheter by malposition, blood, or kinking is the first diagnosis that must be ruled out and corrected immediately if confirmed. When the catheter is patent, obstruction from the surgical field must be considered dependent upon the procedure.

Creatinine

Creatine phosphate in muscle transfers high-energy phosphate to ADP, creating ATP necessary for contraction, and creatine. Creatinine results from the metabolism of creatine in the liver. Serum creatinine is a reasonable approximation of GFR since it is freely filtered by the glomerulus, is soluble, distributes through the total body water, and is not reabsorbed by the tubules. Creatinine varies with muscle mass, rate of catabolism, protein intake, and physical activity. Low GFR tends to overestimate renal function since little creatinine is secreted. The relationship between serum creatinine and GFR is inverse and exponential; that is, a doubling of serum creatinine implies a halving of GFR. The normal serum creatinine range is 0.5 to 1.2 mg/dL. Muscle mass must be taken into consideration since a normal creatinine in a malnourished, cachectic patient may reflect reduced GFR.

Blood Urea Nitrogen

Urea is formed in the liver by the deamination of amino acids and conversion to ammonia by the arginine cycle. It is not an indicator of GFR since it is rapidly reabsorbed by the tubules. Absorption of blood from the gastrointestinal tract, steroids, and sepsis may increase the blood urea nitrogen (BUN), whereas malnutrition or liver disease might result in its decrease. The normal ratio of BUN to serum creatinine ratio is between 10 and 15 to 1. The BUN to creatinine ratio may be useful in the diagnosis of renal failure from prerenal causes versus acute tubular necrosis (see Chapter 42).

RENAL CLEARANCE TECHNIQUES

Clearance is the pharmacokinetic measurement of the volume of plasma that is removed of a specific substance over a period of time. Classic renal physiology experiments used the plant polysaccharide that is freely filtered by the glomerulus and not secreted or reabsorbed by the tubules. ^{131}I-iothalamate has the same renal properties as inulin and is used in radiographic studies to assess clearance.[56]

In routine clinical practice, GFR [urine creatinine (mg/dL) × volume of urine (mL)/plasma creatinine (mg/dL)] has been employed. The traditional collection period is 24 hours but since the collection of urine can sometimes be impractical, shorter intervals can be used for estimations. A volume of urine is carefully collected over a defined time period and the creatinine concentration is measured. A comparison is then made with a blood sample that is taken during the midpoint of urine flow to determine the creatinine. The GFR may decrease significantly before serum creatinine increases above normal and can be inaccurate due to its variable tubular secretion, extrarenal elimination, and variable rates of generation. For these reasons, estimated GFR (eGFR) that is based on age, sex, and race is often calculated using either the Modification of Diet in Renal Disease (MDRD) or the Chronic Kidney Disease Epidemiology Collaboration (CKD-EPI) equation.[57]

Both methods normalize for sex, age, and race and are based on a stable steady-state production of creatinine and are not accurate with AKI when creatinine clearance is in flux. The MDRD formula is normalized to an average adult 1.73 m^2 body surface area. The CKD-EPI equation is more accurate for values less than 60 mL/min/1.73 m^2. Clinical laboratories will state which method is used when eGFR is reported. Extremes of muscle mass, pregnancy, dietary intake, and comorbidities are factors that will lead to errors in eGFR. Creatinine clearance is more accurate when drugs are dosed based on renal function.[58]

Measurement of Tubular Function

When oliguria is present, tests of renal tubular function may be useful to distinguish dehydration (prerenal azotemia) from acute tubular necrosis. In dehydration, the tubules function normally to retain Na^+ and water to maintain the blood volume. The osmolality of plasma is 280 to 300 mOs/kg but with dehydration, the urine osmolality can increase to greater than 450 mOs/kg. Acute tubular necrosis is a pathologic state (see Chapter 42) in which the concentrating ability of the tubules is defective. Sodium and water may be lost in the urine if nonoliguric.

The most common method of assessing for tubular concentration ability is the fractional excretion of sodium (FE_{Na}), which is a measure of sodium clearance as a percentage of creatine clearance. FE_{Na} is calculated by the following from simultaneous samples of blood and urine collection:

$$FE_{Na} = (\text{urine Na/plasma Na}) / (\text{urine creatinine/plasma creatinine}) \times 100$$

Effect of Anesthetics on Renal Function

All general anesthetics tend to decrease GFR and intraoperative urine flow as a consequence of decreased cardiac output and arterial blood pressure.[59] Some drugs also decrease RBF, but filtration fraction is usually increased, which implies that angiotensin-induced efferent arteriolar constriction limits the decrease in GFR that resolves after emergence from anesthesia. Any anesthetic technique that induces hypotension will result in decreased urine flow because of altered peritubular capillary hydrostatic gradients, even if renal autoregulation is preserved. Injury to kidneys seldom occurs unless there is preexisting kidney disease, nephrotoxic injury, hypovolemia, or a combination thereof, which will exacerbate renal dysfunction.[60] Volatile anesthetics induce mild to moderate reductions in RBF and GFR, primarily because of their myocardial depression and vasodilatory effects[61] that can be attenuated by prior intravenous hydration. Opioid-based anesthetics are considerably more effective than volatile anesthetics in suppressing the release of catecholamines, angiotensin II, aldosterone, and AVP. Ketamine increases RBF but decreases urine flow rate, possibly through sympathetic activation; it preserves RBF during hemorrhagic hypovolemia.[62]

The potential for AKI after the breakdown of volatile anesthetics to free fluoride ions causing tubular lesions is now of only historical interest.[63] The "older" volatile drug isoflurane produces minimal peak fluoride levels (<4 μm/L).[64] Initial studies of sevoflurane in rats reported nephrotoxicity through the formation of Compound A, a vinyl ether formed by degradation of sevoflurane at low flow through carbon dioxide absorbents.[65] Clinically significant renal injury has not been shown with desflurane, sevoflurane, or propofol in patients even with moderate preexisting renal dysfunction.[66]

There is growing evidence to support anesthetics as agents that ameliorate ischemia-reperfusion injury in the kidney and other organs.[67] The volatile anesthetics desflurane, sevoflurane, isoflurane, and halothane attenuated the increase in serum creatinine compared with pentobarbital or ketamine in animal models.[68] The mechanism is related to an induction of cytoprotective factors and suppression of proinflammatory cytokine and chemokine activation in response to ischemia-reperfusion. There is experimental evidence that propofol can prevent renal ischemia-reperfusion injury through inhibition of oxidative stress pathways.[69]

EFFECTS OF MECHANICAL VENTILATION ON RENAL FUNCTION

Mechanical ventilation and positive end-expiratory pressure (PEEP) may cause decreases in RBF, GFR, sodium excretion, and urine flow rate through changes in hemodynamics.[70] The increased airway and intrapleural pressures lead to decreased venous return, cardiac filling pressures, and cardiac output. Positive pressure ventilation increases inferior vena caval pressure and through increased renal venous pressure, may increase peritubular capillary pressure to increase tubular sodium reabsorption. The decrease in cardiac output and systemic arterial pressure results in a carotid and aortic baroreceptor-mediated increase in sympathetic nerve tone to the kidney, with renal vasoconstriction, antidiuresis, and anti-natriuresis. Volume receptors in the atria respond to decreased filling by decreased ANP secretion, resulting in increased sympathetic tone, renin activation, and AVP activity.

The renin-angiotensin-aldosterone system undoubtedly augments the renal responses to positive pressure ventilation. An increase in PEEP can depress cardiac output, RBF, GFR, and urine volume, and increase renin and aldosterone. Although the extent of depression of renal function depends on the mean airway pressure, there is no difference in creatinine clearance and FE_{Na} between volume-controlled and pressure support ventilation.[71] Permissive hypercapnia as employed during acute respiratory distress syndrome may promote renal vasoconstriction.[70]

Induced Hypotension

During anesthesia with induced hypotension, substantial reduction of GFR and urine flow rate is common. Although earlier studies suggested that hypotensive anesthesia can be well tolerated without permanent impairment of renal function, a more recent retrospective analysis suggests that mean arterial pressures less than 60 mmHg for 11 to 20 min or less than 55 mmHg for more than 10 min are associated with acute kidney injury.[72] Vasodilators used to induce hypotension differ in their effect on RBF. Administration of sodium nitroprusside decreases renal vascular resistance but tends to shunt blood flow away from the kidney. Moreover, its administration is associated with marked renin-angiotensin activation and catecholamine release, which results in rebound hypertension if the infusion is suddenly discontinued. Nitroglycerin decreases RBF less than sodium nitroprusside.[73] The selective DA1-dopaminergic agonist fenoldopam is capable of providing induced hypotension without any significant decrease in RBF.[74] Nicardipine increased creatinine clearance and attenuated the increase in FE_{Na} in patients undergoing spine surgery under deliberate hypotension[75] and improved renal function when given to patients with preexisting renal insufficiency who had robotic-assisted radical prostatectomy.[76]

18 Basic Principles of Pharmacology

TAE KYUN KIM, SHINJU OBARA, and KEN B. JOHNSON

KEY POINTS

- Pharmacokinetics describes the relationship between drug dose and drug concentration in plasma or at the site of drug effect over time. For anesthetic drugs, the processes of distribution and elimination (metabolism and excretion) govern this relationship.
- The time course of intravenously administered drugs is a function of distribution volume and clearance. Estimates of distribution volumes and clearances, pharmacokinetic parameters, are derived from mathematical formulas fit to measured blood or plasma concentrations over time following a known drug dose.
- Front-end kinetics refer to alterations in cardiac output that substantially influence the pharmacokinetic behavior of anesthetic drugs in terms of onset and duration of effect. Context-sensitive decrement time, which is defined as the time required to reach a certain plasma concentration after a termination of long infusion, characterizes the back-end kinetics.
- Hysteresis refers to the time delay between changes in plasma concentration and drug effect. Hysteresis accounts for the time required for drug to diffuse from the plasma to the site of action plus the time required, once drug is at the site of action, to elicit a drug effect.
- Pharmacodynamics describes what the drug does to the body. In particular, pharmacodynamics describes the relationship between drug concentration and pharmacologic effect.
- The effect-site concentration describes a mathematically derived virtual location where an anesthetic drug exerts its effect. This approach cannot describe a mechanism of drug action (e.g., drug-receptor interaction).
- A single anesthetic drug has multiple effects (i.e., analgesia, ventilatory depression, loss of response to laryngoscopy, and changes in the electroencephalogram) that typically occur at various effect-site concentrations.
- The concentration range where changes in drug effect occur is known as the dynamic range. Concentrations outside the dynamic range do not yield much change in drug effect. Levels below the dynamic range are ineffective and those above the dynamic range do not provide additional effect.
- Anesthesia is the practice of applied drug interactions. Anesthetics rarely consist of one drug, but rather a combination of drugs to achieve desired levels of hypnosis, analgesia, and muscle relaxation. Hypnotics, analgesics, and muscle relaxants all interact with one another such that rarely does one drug, when administered in the presence of other drugs, behave as if it were administered alone.
- Pharmacokinetic and pharmacodynamic principles characterize the magnitude and time course of drug effect, but because of complex mathematics, they have limited clinical utility. Advances in computer simulation have brought this capability to the point of real-time patient care in the form of drug displays.
- Special populations: many aspects of a patient's demographics and medical history are considered in finding the *correct dose*. Some of these include age; body habitus; gender; chronic exposure to opioids, benzodiazepines, or alcohol; presence of heart, lung, kidney, or liver disease; and the extent of blood loss or dehydration.
- Some patient characteristics (e.g., obesity and age) influence anesthetic drug behavior, while other patient characteristics (chronic opioid use, hepatic and renal failure) remain poorly described.

Introduction

The basic principles of pharmacology are fundamental to an anesthesia provider's knowledge base. The aim of this chapter is to provide an overview of key principles in clinical pharmacology used to describe anesthetic drug behavior. This chapter is divided into three major sections: pharmacokinetic principles, pharmacodynamic principles, and the importance of patient characteristics. Pharmacokinetics is the relationship between drug administration and drug concentration at the site of action. Core concepts include volumes of distribution, drug clearance, and transfer of drugs between plasma and tissues. The section on pharmacokinetics introduces both the physiologic processes that determine pharmacokinetics and the mathematical models used to relate dose to concentration.

Pharmacodynamics is the relationship between drug concentration and pharmacologic effect. An anesthetic rarely consists of only one drug. In fact, most anesthetics are a combination of several drugs with specific goals in analgesia, sedation, and muscle relaxation. This section reviews common pharmacodynamic interactions and how they influence anesthetic effect.

The last section briefly addresses patient demographics and how they influence anesthetic behavior. When formulating an anesthetic, the following factors need to be considered in determining the correct dose: age; body habitus; gender; chronic exposure to opioids, benzodiazepines, or alcohol; presence of heart, lung, kidney, or liver disease; and the extent of blood loss or dehydration. This section focuses on body habitus and age, both known to influence the pharmacology of many anesthetic drugs and both of which serve as excellent examples of altered pharmacokinetics and pharmacodynamics.

FUNDAMENTAL PHARMACOKINETIC CONCEPTS

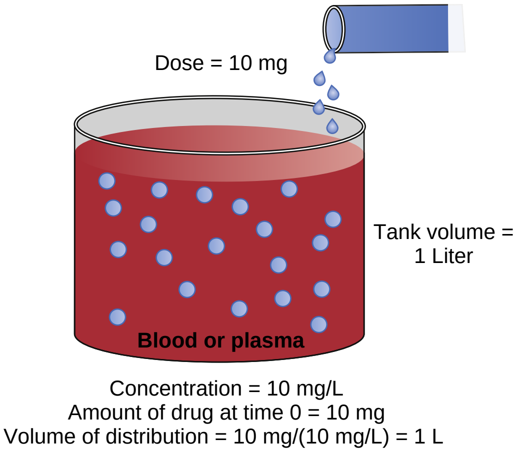
Pharmacokinetics describes the relationship between drug dose and drug concentration in plasma or at the site of drug effect over time. The processes of absorption, distribution, and elimination (metabolism and excretion) govern this relationship. Absorption is not relevant to intravenously administered drugs but is relevant to all other routes of drug delivery. The time course of intravenously administered drugs is a function of distribution volume and clearance. Estimates of distribution volumes and clearances are described by pharmacokinetic parameters. Pharmacokinetic parameters are derived from mathematical formulas fit to measured blood or plasma concentrations over time following a known amount of drug dose.

Volume of Distribution

An over-simplified model of drug distribution throughout plasma and tissues is the dilution of a drug dose into a tank of water. The volume of distribution (Vd) is the apparent size of the tank in which a known amount of drug distributes to produce a measured drug concentration once the drug has had enough time to thoroughly mix within the tank (Fig 18.1). If an injected drug disperses and distributes instantaneously throughout the tank without any drug degradation, the distribution volume is estimated using the simple relationship between dose (e.g., mg) and measured concentration (e.g., mg/L) as presented in Eq. (18.1).

$$\text{Volume of distribution} = \frac{\text{Amount of dose}}{\text{Concentration}} \tag{18.1}$$

With an estimate of tank volume, drug concentration after any bolus dose can be calculated. Human bodies are not like water tanks. As soon as a drug is injected, it begins to be cleared from the body. To account for this in the schematic presented in Fig. 18.1, a faucet is added to the tank to mimic drug elimination from the body (Fig. 18.2). Considering the elimination of drug from the tank and the changes in concentration, the definition of distribution volume in Eq. (18.1) should be refined with the amount of drug and the concentration at a given time t.



Dose = 10 mg
Tank volume = 1 Liter
Blood or plasma
Concentration = 10 mg/L
Amount of drug at time 0 = 10 mg
Volume of distribution = 10 mg/(10 mg/L) = 1 L

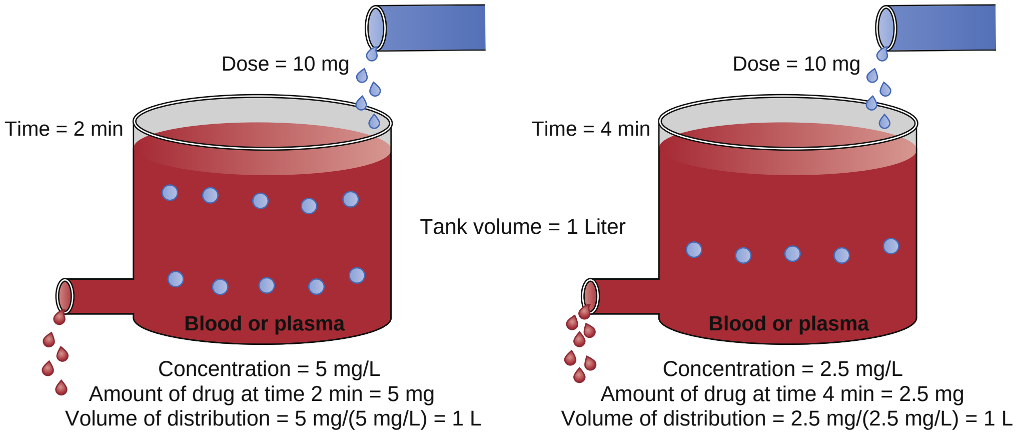
Fig. 18.1 Schematic of a single-tank model of distribution volume. The group of blue drops emerging from the pipe at the top right represent a bolus dose that, when administered to the tank of water, evenly distributes within the tank.

$$\text{Vd} = \frac{\text{Amount (t)}}{\text{Concentration (t)}} \tag{18.2}$$

If drug elimination occurs as a first-order process (i.e., elimination is proportional to the concentration at that time), in a tank model, the volume of distribution calculated by Eq. (18.2) will be constant (Fig. 18.3; see also Fig.18.2). When a drug is administered intravenously, some drug stays in the vascular volume, but most of the drug distributes to peripheral tissues. This distribution is often represented as additional tanks (peripheral distribution volumes) connected to a central tank (blood or plasma volume). Peripheral distribution volumes increase the total volume of distribution (Fig. 18.4). For the calculation of distribution volumes, peripheral tissue concentrations are difficult to measure whereas plasma concentrations are easily measured.

The schematic in Fig. 18.4 presents two tanks that represent plasma and peripheral tissue volumes. The peripheral tank represents the drug volume of distribution in peripheral tissues. There may be more than one peripheral tank (volume) to best describe the entire drug disposition in the body. The size of the peripheral volumes represents a drug's solubility in tissue relative to blood or plasma. The more soluble a drug is in peripheral tissue relative to blood or plasma, the larger the peripheral volumes of distribution.

An important point illustrated in Fig. 18.4 is that drug not only distributes to the peripheral tank and thus increases the volume of distribution, but it also binds to tissue in that tank. This process further lowers the measurable concentration in the central tank. Thus, the total volume of distribution may even be larger than the two tanks added together. In fact, some anesthetics have huge distribution volumes (e.g., fentanyl has an apparent distribution volume of 4 L/kg) that are substantially larger than an individual's vascular volume (0.07 L/kg) or extracellular volume (0.2 L/kg).



Dose = 10 mg
Time = 2 min
Blood or plasma
Concentration = 5 mg/L
Amount of drug at time 2 min = 5 mg
Volume of distribution = 5 mg/(5 mg/L) = 1 L
Tank volume = 1 Liter
Dose = 10 mg
Time = 4 min
Blood or plasma
Concentration = 2.5 mg/L
Amount of drug at time 4 min = 2.5 mg
Volume of distribution = 2.5 mg/(2.5 mg/L) = 1 L

Fig.18.2 Schematic of a single-tank model of elimination as a first-order process (eliminated at a rate of 50% to the amount of drug present at every two minutes). At 2 minutes *(left panel)* and 4 minutes *(right panel)* following a 10-mg drug bolus, tank concentrations are decreasing from 5 to 2.5 mg/mL. Accounting for elimination, estimates of the distribution volume at each time point are both 1 L.

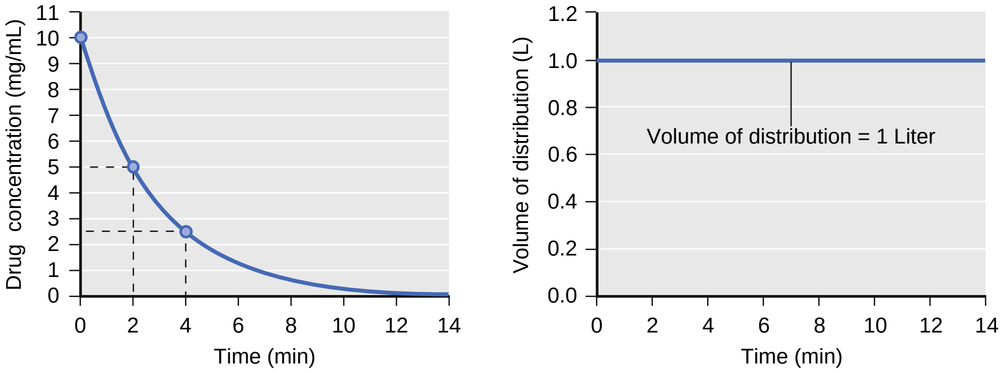


Fig.18.3 Simulation of concentration *(left panel)* and distribution volume *(right panel)* changes over time following a bolus dose for a single-tank (one-compartment) model. The distribution volume remains constant throughout.

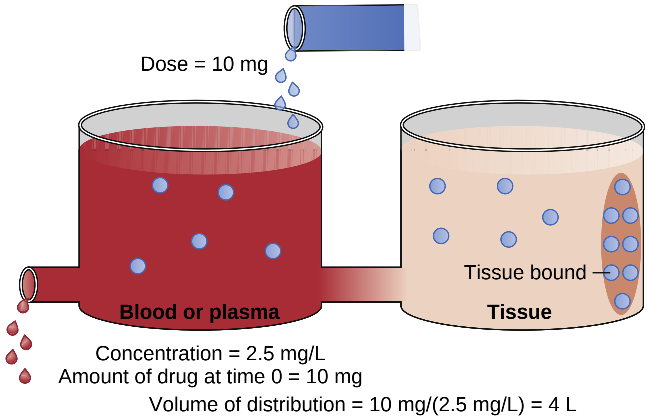

Dose = 10 mg
Blood or plasma
Tissue bound
Tissue
Concentration = 2.5 mg/L
Amount of drug at time 0 = 10 mg
Volume of distribution = 10 mg/(2.5 mg/L) = 4 L

Fig. 18.4 Schematic of a two-tank model. The total volume of distribution consists of the sum of the two tanks. The brown ellipse in the peripheral volume represents tissue that binds up drugs. The measured concentration in the blood or plasma is 2.5 mg/mL just after a bolus dose of 10 mg. Using Fig. 18.1, this leads to a distribution volume of 4 L.

With additional distribution volumes, the overall volume of distribution can change over time and is a function of how drug is administered as well (e.g., as a bolus or a continuous infusion). For example, consider simulations of concentrations and distribution volumes over time following a bolus dose or a continuous infusion of an intravenous anesthetic as presented in Fig. 18.5. For a bolus dose, assume that the volume of distribution is 1 L at time = 0 and that it then increases to 14 L as the plasma concentration falls over the next 10 minutes. The increase of the distribution volume is due to the distribution of drug to peripheral tissue and a decrease in the plasma concentration. For a constant infusion, assume the volume of distribution is again 1 L at time = 0 and that it then increases to 5 L as the plasma concentrations also increase to a steady-state concentration over the next several hours. This is known as the steady-state volume of distribution. It is estimated as the sum of the central and peripheral apparent distribution volumes.

Clearance

Clearance describes the rate of drug removal from the plasma/blood. Two processes contribute to drug clearance: systemic (removal from the tank) and intercompartmental (between tanks) clearance (Fig. 18.6). Systemic clearance permanently removes drug from the body, either by eliminating the parent molecule or by transforming it into metabolites. Intercompartmental clearance moves drug between plasma and peripheral tissue tanks. By way of clarification, in this chapter, the words compartment and tank are interchangeable.

Clearance is defined in units of flow, that is, the volume completely cleared of drug per unit of time (e.g., L/min).

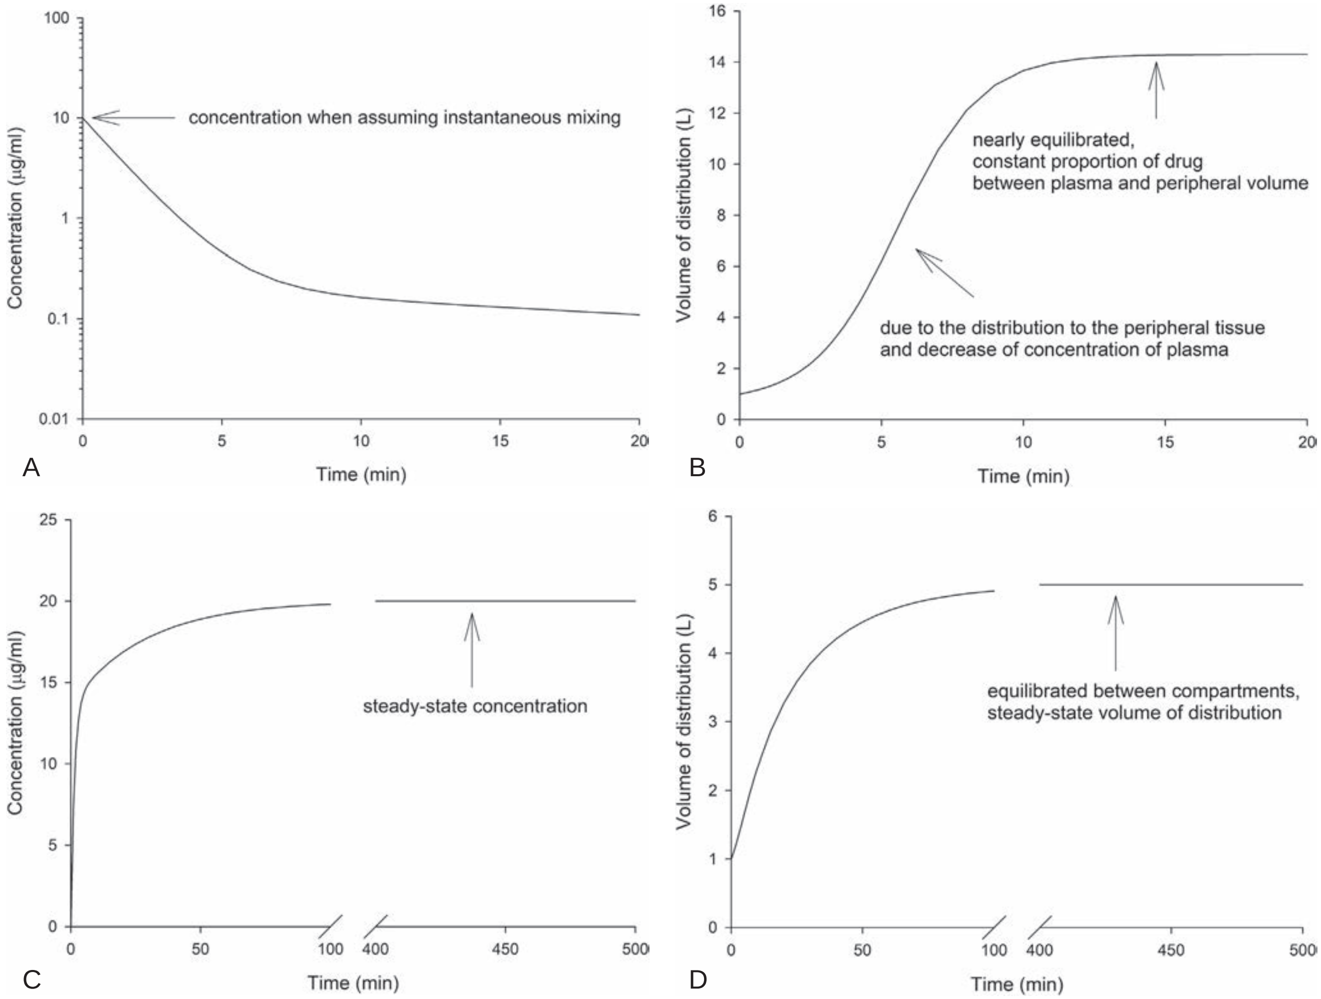

Fig. 18.5 Simulation of concentration and apparent distribution volume changes over time following a bolus dose for a two-tank (two-compartment) model. Panels A and C present drug concentrations over time. Panels B and D present the apparent distribution volume over time.

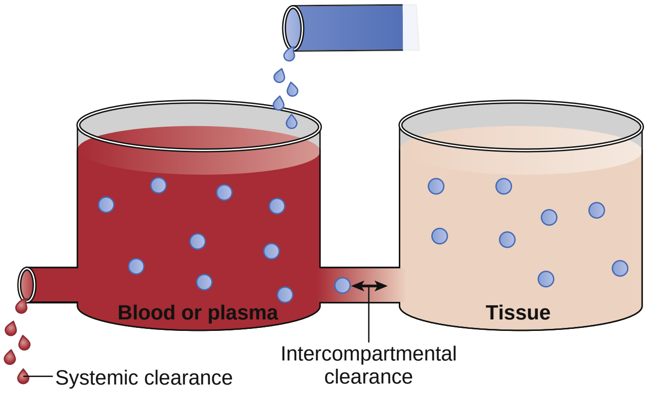

Fig. 18.6 Schematic of a two-tank model illustrating two sources of drug removal from the central tank (blood or plasma): systemic and intercompartmental clearance.

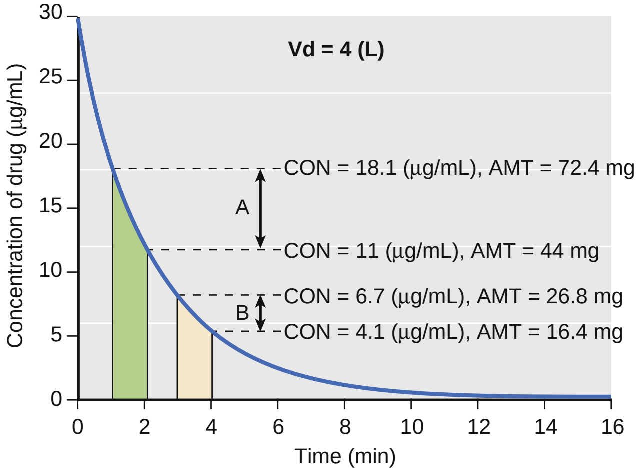

Fig.18.7 Simulation of drug concentration changes when a drug is administered to a single-tank model with first-order elimination (see Fig. 18.2). The concentration changes for two time windows are labeled with dashed lines from 1 to 2 minutes (time window *A*) and from 3 to 4 minutes (time window *B*), respectively. The concentrations *(CON)* at the beginning and end of each time window are used to calculate the amount *(AMT)* of drug that is eliminated (see text). *Vd*, Volume of distribution.

Clearance is not to be confused with elimination rate (e.g., mg/min). The elimination rate is not an accurate method of describing the mass of drug removed over time. For example, assuming a first-order process, when plasma concentrations are high, the rate of drug elimination is high. When low, the rate is also low. Clearance is a better descriptor as it is independent of drug concentration.

To illustrate this point, consider the simulation presented in Fig. 18.7. In this simulation, the total amount of drug at each time can be calculated from the known volume of distribution and measured concentration. The concentration change in time window A is larger than in time window B even though they are both 1 minute in duration. The elimination rates are 28.4 and 10.4 mg/min for time windows A and B, respectively. They are different, and neither can be used as a parameter to represent a measure of drug removal from the body. Because of this limitation with elimination rate, clearance was developed to provide a single number to describe the decay in drug concentration presented in Fig. 18.7.

For discussion purposes, assume that concentration is the power necessary to push drug out of the water tank. The higher the concentration, the larger the amount of drug eliminated. To standardize the elimination rate, the eliminated amount of drug is scaled to concentration. For example, when the elimination rate in time window A (28.4 mg/min) is scaled to the concentration at the middle of the time window (14.2 μg/mL), the clearance is 2 L/min. When the elimination rate in time window B (10.4 mg/min) is scaled to the concentration at the middle of the time window (5.2 μg/mL), the clearance is again 2 L/min. If the time interval is narrowed so that the time window approaches zero, the definition of clearance becomes:

$$\text{Clearance} = \frac{\frac{dA(t)}{dt}}{C(t)} \tag{18.3}$$

where dA(t)/dt is the rate of drug elimination at given time t, and C(t) is the corresponding concentration at that time. Rearranging Eq. (18.3) and integrating both numerator and denominator, the following relationship holds:

$$\text{Clearance} = \frac{\int_0^\infty dA(t)}{\int_0^\infty C(t)\,dt} \tag{18.4}$$

because the term $\int_0^\infty dA(t)$ is equal to the total amount of drug eliminated and $\int_0^\infty C(t)\,dt$ is the area under curve (AUC) in concentration versus time plot, then the following equation can be derived:

$$\text{Clearance} = \frac{\text{Dose}}{\text{AUC}} \tag{18.5}$$

With long infusions, drug concentrations reach a steady-state condition where the rate of drug elimination $\left(\frac{dA(t)}{dt}\right)$ is in equilibrium with the rate of drug administration (infusion rate). Clearance in a steady-state condition can be obtained using Eq. (18.3) as follows:

$$\text{Clearance} = \frac{\text{Infusion rate}}{\text{Css}} \tag{18.6}$$

where Css is the plasma concentration at steady state.

To illustrate the relationship between clearance and volume of distribution, consider the following simulation using a generic drug dosed in milligrams into a single compartment (tank) representing the distribution volume that has a clearance of 1 L/min. Assume that when drug is administered, the tank is well stirred and has instantaneous mixing throughout the entire volume. Assume the distribution volume is 4 L, the total dose of drug is 64 mg, and that drug elimination is proportional to the amount of drug present inside the tank at any given time. This rate of drug elimination is known as first-order elimination kinetics. When the drug is injected into the 4 L distribution volume, the drug will instantly evenly distribute throughout

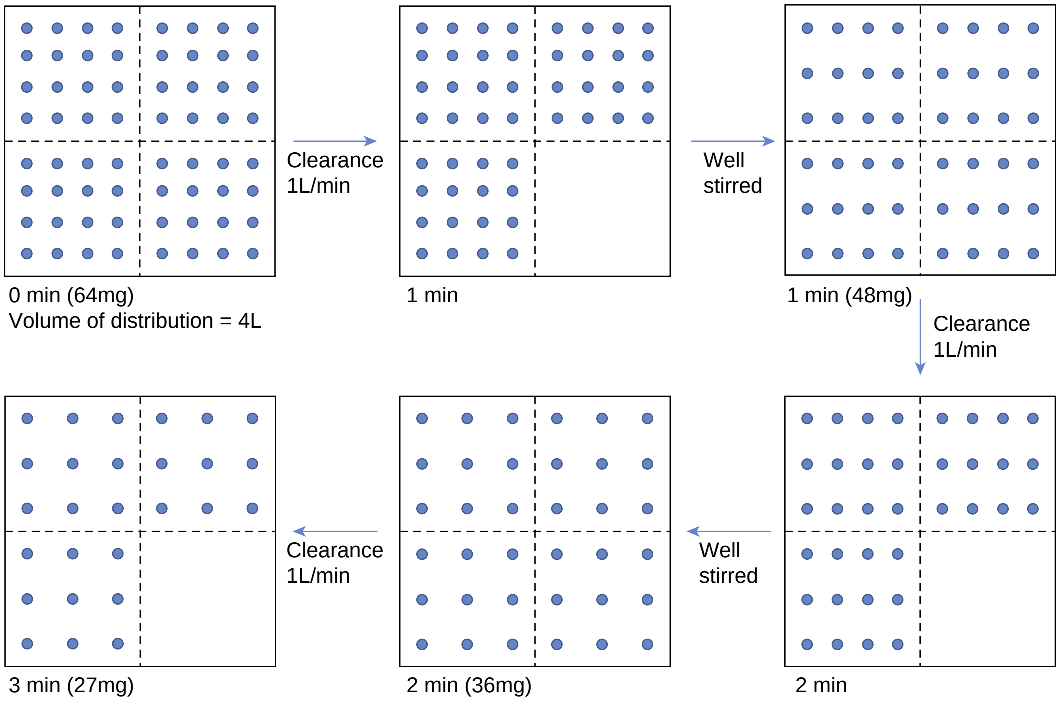

Fig. 18.8 Schematic representation of relationship among clearance, volume of distribution, and elimination rate constant. A generic drug dose of 64 mg is administered into a single compartment volume of 4 L that has a clearance of 1 L/min. Drug elimination is proportional to the amount of drug present inside the compartment at any given time, otherwise known as first-order elimination kinetics. At 1-minute intervals, one of the 4 L is cleared along with all drug contained in that liter. The drug amount decreases by 16, 12, and 9 mg at 1, 2, and 3 minutes.

the compartment (Fig. 18.8). With a clearance of 1 L/min, the amount of drug distributed to one fourth of compartment volume (1 L) will be cleared every minute. In the first minute, 16 mg drug is cleared. The remaining 48 mg will be redistributed evenly throughout the compartment. For the next minute, one fourth of the compartment volume (1 L) is again cleared. In the second minute, 12 mg of drug is cleared. This process repeats every minute. When assuming instantaneously mixing, the ratio of the amount of drug removed within the cleared portion of the distribution volume to the amount of drug within the total distribution volume will remain the same as illustrated in Eq. (18.7).

$$\frac{16\text{mg}}{64\text{mg}} = \frac{12\text{mg}}{48\text{mg}} = \frac{9\text{mg}}{36\text{mg}} = \frac{\text{cleared volume}}{\text{volume of distribution}} \qquad (18.7)$$

This ratio, known as the elimination rate constant (k), is described in Eq. (18.8).

$$\frac{\text{CL}}{\text{Vd}} = \text{k or CL} = \text{Vd} \times \text{k} \qquad (18.8)$$

Where CL is clearance with units of volume/time (L/min), Vd is the compartment distribution volume with units of liters (L), and k is the first-order elimination rate constant with units of inverse time (min^{-1}).

Physiologic Model for Clearance

Drug extraction by metabolic organs is illustrated in Fig. 18.9. This model contains a metabolic organ system responsible for drug elimination. According to mass balance, the rate at which drug flows *out* of metabolic organs is the rate at which drug flows *into* them minus the metabolic rate. The elimination rate (dA/dt) can be expressed as Q (C_{in} − C_{out}). Rearranging C(t) in Eq. (18.3) with C_{in}, clearance can be expressed as

$$\text{Clearance} = \frac{Q\,(C_{in} - C_{out})}{C_{in}} \qquad (18.9)$$

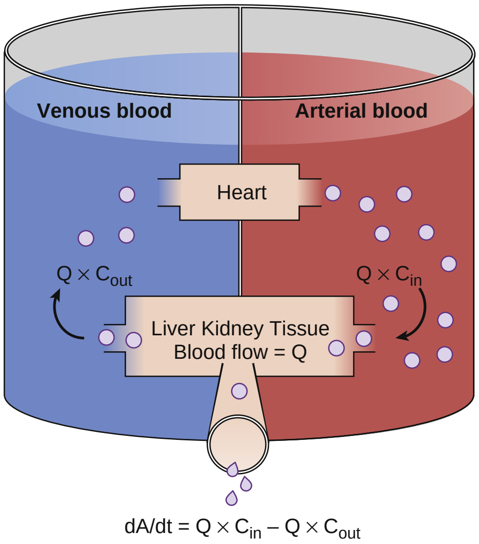

Fig. 18.9 Schematic of drug extraction. Q indicates blood flow. C_{in} and C_{out} indicate drug concentrations presented to and leaving metabolic organs. A indicates the amount of drug, and dA/dt is the drug elimination rate.

where Q is the blood flow to metabolic organs, C_{in} is the concentration of drug delivered to metabolic organs, and C_{out} is the concentration of drug leaving metabolic organs.

The fraction of inflowing drug extracted by the organ is $\frac{C_{in} - C_{out}}{C_{in}}$. This is called the extraction ratio (ER). Clearance can be estimated as organ blood flow multiplied by the ER. Eq. (18.9) can be simplified to

$$\begin{aligned}\text{Clearance} &= \frac{Q\,(C_{in} - C_{out})}{C_{in}} \\ &= Q \times \frac{C_{in} - C_{out}}{C_{in}} = Q \times \text{ER} \qquad (18.10)\end{aligned}$$

The total clearance is the sum of each clearance by metabolic organs such as the liver, kidney, and other tissues.

Hepatic clearance has been well characterized. For example, the relationship among clearance, liver blood flow, and the ER is presented in Fig. 18.10.[1] For drugs with an ER of nearly 1 (e.g., propofol), a change in liver blood flow produces a nearly proportional change in clearance. For drugs with a low ER (e.g., alfentanil), clearance is nearly independent of the rate of liver blood flow. If nearly 100% of the drug is extracted by the liver, this implies that the liver has a very large metabolic capacity for the drug. In this case, the rate-limiting step in metabolism is the flow of drug to the liver, and such drugs are said to be "flow limited." As a consequence, any reduction in liver blood flow due to circulatory effects of anesthetic agents or changes in circulatory volumes in cases of perioperative bleeding or other situations of excessive fluid loss can be expected to reduce liver-dependent drug clearance. However, moderate changes in hepatic metabolic function per se will have little

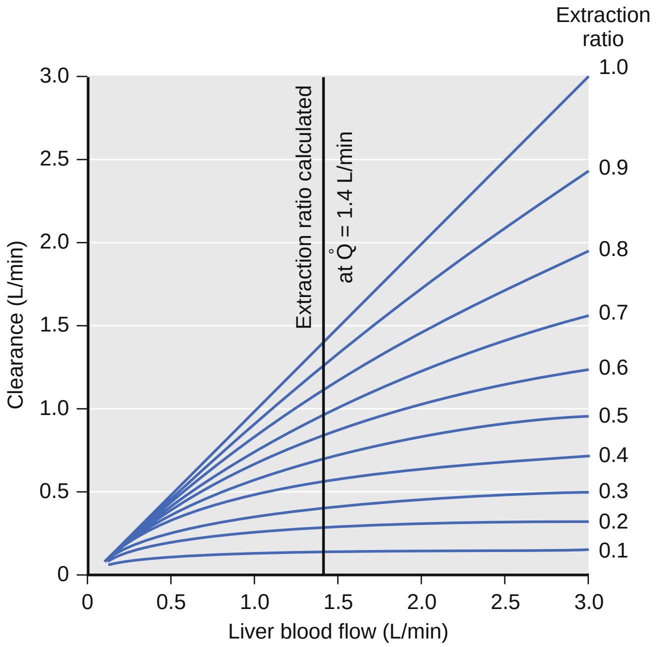

Fig. 18.10 Relationship among liver blood flow (Q), clearance, and extraction ratio. For drugs with a high extraction ratio, clearance is nearly identical to liver blood flow. For drugs with a low extraction ratio, changes in liver blood flow have almost no effect on clearance. (From Wilkinson GR, Shand DG. Commentary: a physiological approach to hepatic drug clearance. *Clin Pharmacol Ther.* 1975;18:377–390.)

impact on clearance because hepatic metabolic capacity is overwhelmingly in excess of demand.

For many drugs (e.g., alfentanil), the ER is considerably less than 1. For these drugs, clearance is limited by the capacity of the liver to take up and metabolize drug. These drugs are said to be "capacity limited." Clearance will change in response to any change in the capacity of the liver to metabolize such drugs, as might be caused by liver disease or enzymatic induction. However, changes in liver blood flow caused by the anesthetic regimen or other changes in splanchnic circulation usually have little influence on clearance because the liver handles only a fraction of the drug that it sees.

Although most anesthetic drugs are cleared by hepatic metabolism, remifentanil, succinylcholine, and esmolol are cleared in the plasma and tissues by ester hydrolysis, and pancuronium is cleared via the kidney. The relationship between metabolism and clearance is complex.

Hepatic Biotransformation

Most anesthetic drugs are cleared by hepatic biotransformation. The synthetic pathways for biotransformation are covered in detail in many biochemistry texts. Briefly, the liver metabolizes drugs through oxidation, reduction, hydrolysis, or conjugation. Oxidation and reduction occur in the cytochrome P450 system. These enzymes can be induced by exposure to certain drugs (e.g., the herbal remedy St. John's wort) and increase the liver's intrinsic metabolic capacity. Other drugs or hepatic disease can inhibit these enzymes (e.g., selected calcium channel blockers and selected antibiotics). Routes of oxidative metabolism include hydroxylation, dealkylation, deamination, desulfuration, epoxidation, and dehalogenation. Conjugation and hydrolysis often occur outside the P450 system, although glucuronidation involves the P450 system as well. The effect of conjugation is to transform hydrophobic molecules into water-soluble molecules through the addition of polar groups and thus render the metabolites easier to excrete via the kidneys. The metabolites generated by the liver are generally inactive, although some drugs (e.g., morphine, midazolam) have metabolites that are as potent as the parent drug. Genetic polymorphism can occur in all of these pathways, and this accounts for part of the variability in clearance in the population.

Pharmacokinetic Models

To create a framework from which to compare drugs and describe drug behavior, pharmacologists developed pharmacokinetic models to characterize drug concentrations as a function of time. These models provide estimates of drug concentrations over time in response to dosing regimens (e.g., bolus vs. infusion). Several types of pharmacokinetic models have been developed. Examples include complex physiologic models and the more common compartmental models.

Physiologic Models

Physiologic models are based on organ and tissue physiologic and anatomic data. Drug concentrations into and out of an organ, organ blood flow, and organ drug distribution volume are required. Capturing these metrics from all organs is nearly impossible in humans and very challenging in animal models. If obtained, this data is used to estimate volumes and clearances for each organ in the body. Individual organ models are assembled into a whole organism physiological model.[2] Once assembled, the combined models are complex and mathematically cumbersome. They may not offer a better prediction of plasma drug concentrations over time than simple compartmental models. If the intent of the model is to explore the ability of possible dosing regimens to achieve therapeutic plasma drug concentrations, compartmental models are usually adequate.

Compartmental Models

Compartmental models are built on the same basic concepts as physiologic models, but with significant simplifications. Compartment pharmacokinetic models are strictly empirical. They are based on fitting equations to measured plasma concentrations following a known dose. Kinetic models are transformed into models that characterize changes over time in terms of volumes and clearances. Part of the continuing popularity of pharmacokinetic models is that they can be transformed from an unintuitive exponential form to a more intuitive compartmental form as shown in Fig. 18.11.

Compartment models used to describe anesthetic drugs typically consist of one, two, or three compartments corresponding to the number of exponents in an equation needed to best fit the plasma versus concentration data (see Fig. 18.11). Exponents are difficult to work with and have little clinical meaning. Thus, they are converted into fictitious volumes and clearances. For example, in a three-compartment model, there is a central compartment and two peripheral compartments. The sum of the all volumes is the volume of distribution at steady state. Drug clearance

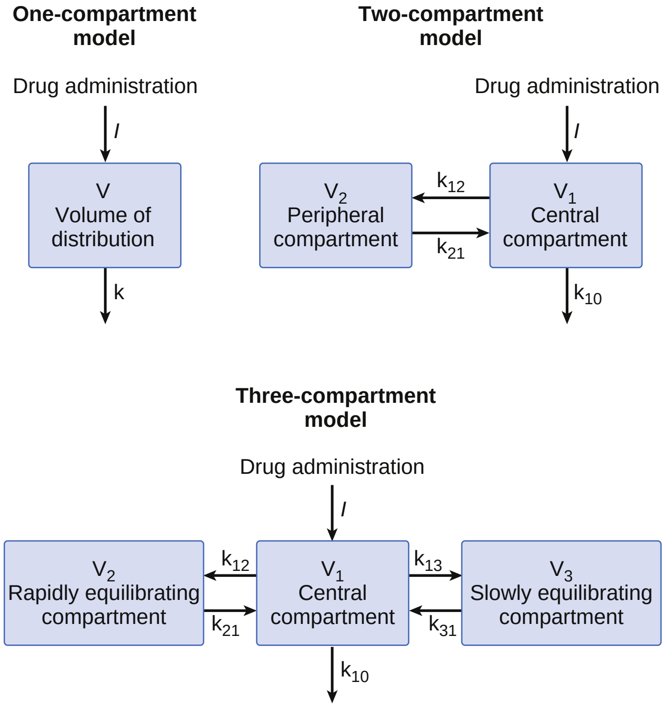

Fig. 18.11 One-, two-, and three-compartment mammillary models.

from the central compartment to the outside is the central clearance. Central clearance accounts for both metabolism and excretion. Clearances between the central and peripheral compartments is the "intercompartmental" clearance. Micro rate constants, expressed as k_{ij}, define the rate of drug transfer from compartment i to compartment j. For example, k_{10} is the micro rate constant describing drug transfer from central compartment to the outside. The intercompartmental micro rate constants (k_{12}, k_{21}, etc.) describe movement of drug between the central and peripheral compartments. Each peripheral compartment has at least two micro rate constants, one for drug entry and one for drug exit. The micro rate constants for the two- and three-compartment models are presented in Fig. 18.11.

Zero Versus First-Order Kinetics

Drug elimination can have one of two profiles, zero- and first-order kinetics. With zero-order kinetics, drug is eliminated at a constant rate. With first-order kinetics, drug is eliminated at a rate proportional to the amount of drug present at that time. These rates are expressed using the following equations.

$$\frac{dA(t)}{dt} = -k_0 \text{ for zero order kinetics} \qquad (18.11)$$

$$\frac{dA(t)}{dt} = -k_1 E(t) \text{ for first-order kinetics} \qquad (18.12)$$

where A(t) is the amount of drug at time t, dA(t) is the change in drug amount at time t. $-k_0$ is the zero-order elimination rate constant. Its units are mass/time (e.g., mg/min). $-k_1$ is the first-order elimination rate constant. Its units are the reciprocal time 1/time, (e.g., min^{-1}). Most anesthetic drugs have first-order kinetics. When the processes responsible for metabolism are saturated, the kinetics could change from first to zero order.

ONE-COMPARTMENT MODEL

For a one-compartment model with first-order kinetic elimination, the amount of drug at a given time t is described by Eq. (18.13).

$$A(t) = A_0 e^{-kt} \qquad (18.13)$$

where A_0 is the initial drug amount (i.e., the initial dose), k is the first-order kinetic elimination rate constant. Note that k must be greater than 0. With this equation, there is an exponential decrease in drug amount.

The distribution volume (Vd) is a function of drug concentration and the total amount of drug in the compartment. Dividing Eq. (18.13) on both sides by Vd yields the following equation:

$$\frac{A(t)}{Vd} = \frac{A_0}{Vd} e^{-kt} \qquad (18.14)$$

Drug concentration can be derived from this relationship with Eq. (18.15):

$$C(t) = C_0 \times e^{-kt} \qquad (18.15)$$

where C(t) is the concentration at time t, C_0 is the initial concentration at time 0.

Taking the natural logarithm on both sides, the following expression is obtained:

$$\log C(t) = \log C_0 - kt \qquad (18.16)$$

A plot of this equation shows a straight line with slope of –k and intercept of log C_0. To yield the time required for the concentration to decrease by half, replacing log C(t) in Eq. (18.16) to log $C_0/2$ and rearranging gives:

$$\log \frac{C_0}{2} = \log C_0 - kt \qquad (18.17)$$

Solving this equation gives

$$t_{1/2} = \frac{0.693}{k} \qquad (18.18)$$

where $t_{1/2}$ is the elimination half-life.

Multicompartment Models

Plasma concentrations over time after an intravenous bolus resemble the curve in Fig. 18.12. This curve has the characteristics common to most drugs when given by intravenous bolus. First, the concentrations continuously decrease over time. Second, the rate of decline is initially steep but continuously becomes less steep, until we get to a portion that is "log-linear." For many drugs, three distinct phases can be distinguished, as illustrated in Fig. 18.12. A "rapid-distribution" phase *(blue line)* begins immediately after bolus injection. Very rapid movement of the drug from plasma to the rapidly equilibrating tissues characterizes this phase. Frequently there is a second "slow-distribution" phase *(red line)*, which is characterized by movement of drug into more slowly equilibrating tissues and return of drug to plasma from the most rapidly equilibrating tissues. The terminal phase *(green line)* is a straight line when plotted on a semilogarithmic graph. The terminal phase is often called the "elimination phase" because the primary mechanism for decreasing drug concentration during the terminal phase is elimination of drug from the body. The distinguishing

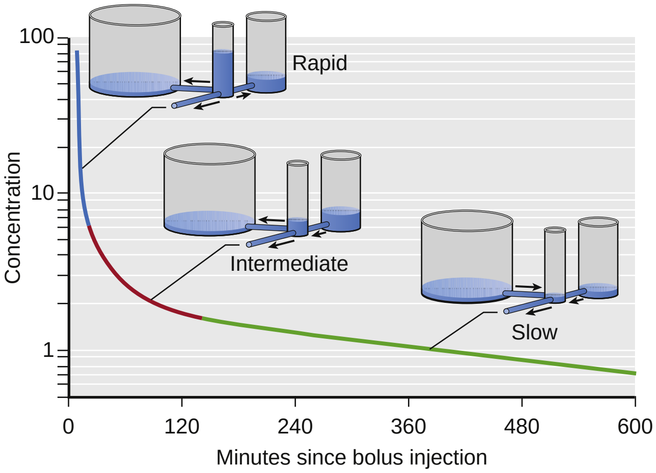

Fig. 18.12 Hydraulic model of fentanyl pharmacokinetics. Drug is administered into the central tank, from which it can distribute into two peripheral tanks, or it may be eliminated. The volume of the tanks is proportional to the volumes of distribution. The cross-sectional area of the pipes is proportional to clearance. (From Youngs EJ, Shafer SL. Basic pharmacokinetic and pharmacodynamic principles. In: White PF, ed. *Textbook of Intravenous Anesthesia*. Baltimore: Williams & Wilkins; 1997.)

characteristic of the terminal elimination phase is that the plasma concentration is lower than tissue concentrations and the relative proportion of drug in plasma and peripheral volumes of distribution remains constant. During this terminal phase, drug returns from the rapid- and slow-distribution volumes to plasma and is permanently removed from plasma by metabolism or excretion.

The presence of three distinct phases after bolus injection is a defining characteristic of a three-compartment model.[3] A useful metaphor in describing the features of this model is hydraulics. This model has three tanks corresponding (from left to right) to the slowly equilibrating peripheral compartment, the central compartment (the plasma, into which drug is injected), and the rapidly equilibrating peripheral compartment. The horizontal pipes represent intercompartmental clearance or (for the pipe draining onto the page) metabolic clearance. The volumes of each tank correspond to the volumes of each compartment. The cross-sectional areas of the pipes correlate with fentanyl systemic and intercompartmental clearance. The height of water in each tank corresponds to drug concentration.

By using this hydraulic model, we can follow the processes that decrease drug concentration over time after bolus injection. Initially, drug flows from the central compartment to both peripheral compartments via intercompartmental clearance and completely out of the model via metabolic clearance. Because there are three places for drug to go, the concentration in the central compartment decreases very rapidly. At the transition between the blue line and the red line, a change occurs in the role of the most rapidly equilibrating compartment. At this transition, the concentration in the central compartment falls below the concentration in the rapidly equilibrating compartment, and the direction of flow between them is reversed. After this transition *(red line)*, drug in plasma has only two places to go: into the slowly equilibrating compartment or out the drain pipe. These processes are partly offset by the return of drug to plasma from the rapidly equilibrating compartment. The net effect is that once the rapidly equilibrating compartment has come to equilibration, the concentration in the central compartment falls far more slowly than before.

Once the concentration in the central compartment falls below both the rapidly and slowly equilibrating compartments *(green line)*, the only method of decreasing the plasma concentration is metabolic clearance, the drainpipe. Return of drug from both peripheral compartments to the central compartment greatly slows the rate of decrease in plasma drug concentration.

Curves that continuously decrease over time, with a continuously increasing slope (i.e., curves that look like Fig. 18.12), can be described by a sum of negative exponentials. In pharmacokinetics, one way of denoting this sum of exponentials is to say that the plasma concentration over time is

$$C(t) = Ae^{-\alpha t} + Be^{-\beta t} + Ce^{-\gamma t} \qquad (18.19)$$

where t is the time since the bolus, C(t) is the drug concentration after a bolus dose, and A, α, B, β, C, and γ are parameters of a pharmacokinetic model. A, B, and C are called coefficients, whereas α, β, and γ are called exponents. After a bolus injection, all six of the parameters in Eq. (18.19) will be greater than 0.

Special significance is often ascribed to the smallest exponent. This exponent determines the slope of the final log-linear portion of the curve. When the medical literature refers to the half-life of a drug, unless otherwise stated, the half-life will be the terminal half-life. Some literature occasionally refers to the half-life of the initial distribution phase as distribution half-life. The terminal half-life sets an upper limit on the time required for the concentrations to decrease by 50% after drug administration. Usually, the time needed for a 50% decrease will be much faster than that upper limit.

Special Interests in Anesthetic Pharmacokinetics

Front-End Kinetics

Front-end kinetics refers to the description of intravenous drug behavior immediately following administration. How a drug rapidly moves from the blood into peripheral tissues directly influences the peak plasma drug concentration. The amount of drug that moves to the peripheral tissue commonly surpasses the amount that is eliminated during the first few minutes after drug administration. As an example, consider a simulation of a propofol bolus that plots the accumulation of propofol in peripheral tissues and the amount eliminated over time (Fig. 18.13). During the first 4 minutes, the amount distributed to the peripheral tissue is larger than the amount eliminated out of the body. After 4 minutes, the amounts reverse.

With compartmental models, an important assumption is that an intravenous bolus instantly mixes in the central volume, with the peak concentration occurring at the moment of injection without elimination or distribution to peripheral tissues. For simulation purposes, the initial concentration and volume of distribution at time = 0 are extrapolated as if the circulation had been infinitely fast. This, of course, is not real. If drug is injected into an arm

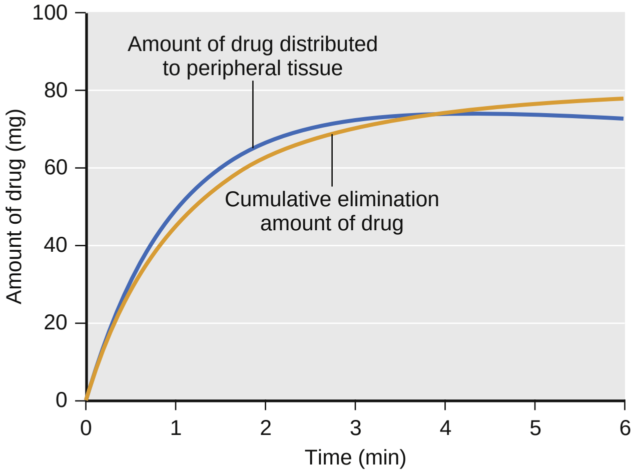

Fig.18.13 Simulation of propofol accumulation in the peripheral tissues *(blue line)* and the cumulative amount of propofol eliminated *(gold line)* following a 2-mg/kg propofol bolus to a 77-kg (170-lb), 53-year-old male who is 177 cm (5 ft 10 inch) tall, using published pharmacokinetic model parameters.[32] Drug indicates propofol.

vein and the initial concentration is measured in a radial artery, drug appears in the arterial circulation 30 to 40 seconds after injection. The delay likely represents the time required for drug to pass through the venous volume of the upper part of the arm, heart, great vessels, and peripheral arterial circulation. More sophisticated models (e.g., a recirculatory model)[4] account for this delay and are useful when characterizing the behavior of a drug immediately following bolus administration such as with induction agents where the speed of onset and duration of action are of interest (Fig. 18.14).

Back-End Kinetics

Using estimates of distribution volume and clearance, back-end kinetics is a useful tool that describes the behavior of intravenous agents when administered as continuous infusions. Back-end kinetics provides descriptors of how plasma drug concentrations decrease once a continuous infusion is terminated. An example is decrement time, which predicts the time required to reach a certain plasma concentration once an infusion is terminated. Decrement times are a function of infusion duration. Consider the example of decrement times for a set of continuous target- controlled infusions (TCIs; Fig. 18.15). In this simulation, TCI of propofol is set to maintain a concentration of 4 µg/mL for 30, 60, and 120 minutes. Once the infusion is stopped, the time to reach 0.5 µg/mL is estimated. As illustrated, the longer the infusion, the longer the time required to reach 0.5 µg/mL. This example demonstrates how drugs accumulate in peripheral tissues with prolonged infusions. This accumulation prolongs the decrement time.

Another use of decrement times is as a tool to compare drugs within a drug class (e.g., opioids). As a comparator, plots of decrement times are presented as a function of infusion duration. When used this way, decrement times are determined as the time required to reach a target percentage of the concentration just before the termination of a continuous infusion. Examples of 50% and 80% decrement times for selected opioids and sedatives are presented in Fig. 18.16. Of note, for shorter infusions, the decrement times are similar for both classes of anesthetic drugs. Once infusion duration exceeds 2 hours, the decrement times vary substantially. A popular decrement time is the 50% decrement time, also known as the context-sensitive half-time.[5] The term "context-sensitive" refers to infusion duration and the term "half-time" refers to the 50% decrement time.

Hysteresis

Hysteresis refers to the time delay between changes in plasma concentration and drug effect. Hysteresis accounts for the time required for drug to diffuse from the plasma to the site of action plus the time required, once drug is at the site of action, to elicit a drug effect. A simulation of various propofol bolus doses and their predicted effect on bispectral index are presented in Fig. 18.17. Of note, the time to peak effect for each dose is identical (approximately 1.5 minutes following the peak plasma concentration). The difference between each dose is the magnitude and duration of effect. A key principle here is that when drug concentrations are in flux (e.g., during induction and emergence), changes in drug effect will lag behind changes in plasma drug concentration. This lag between the plasma concentration and

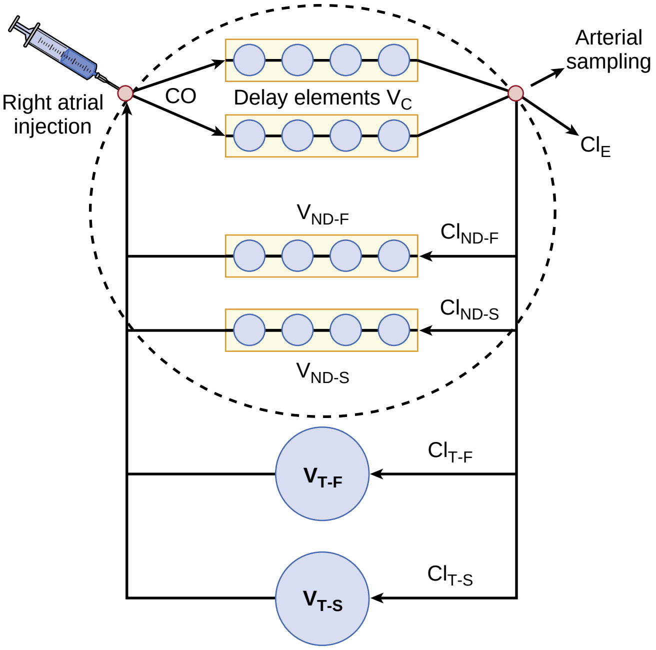

Fig. 18.14 A recirculatory model accounting for cardiac output *(CO)*, transit delays, pulmonary uptake (delay elements V and C), and nondistributive mixing pathways (V_{ND} and Cl_{ND}). All the components within the *dashed circle* are required to accurately model the central volume of distribution. In most situations, this complexity is not required, and the simpler approach of assuming instantaneous mixing within the central volume is an adequate approximation. Cl_{ND-F}, Fast nondistributive clearance; Cl_{ND-S}, slow nondistributive clearance; Cl_{T-F}, fast tissue clearance; Cl_{T-S}, slow tissue clearance; V_{ND-F}, fast nondistributive volume; V_{ND-S}, slow nondistributive volume; V_{T-F}, fast tissue volume; V_{T-S}, slow tissue volume. (From Krejcie TC, Avram MJ, Gentry WB. A recirculatory model of the pulmonary uptake and pharmacokinetics of lidocaine based on analysis or arterial and mixed venous data from dogs. J Pharmacokinet Biopharm. 1997;25:169–190.)

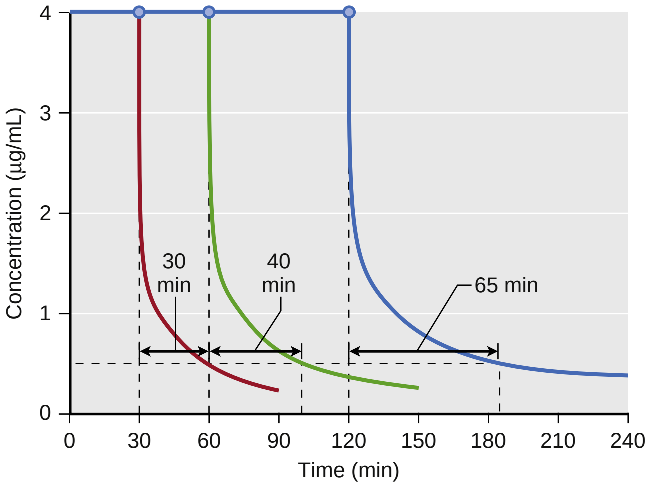

Fig. 18.15 Simulation of decrement times for a target-controlled infusion set to maintain a target propofol concentration of 4 µg/mL for 30, 60, and 120 minutes. Once terminated, the time required to reach 0.5 µg/mL was 30, 40, and 65 minutes for each infusion, respectively. Simulations of the decrement times used a published pharmacokinetic model. (From Schnider TW, Minto CF, Gambus PL, et al. The influence of method of administration and covariates on the pharmacokinetics of propofol in adult volunteers. *Anesthesiology*. 1998;88(5):1170–1182.)

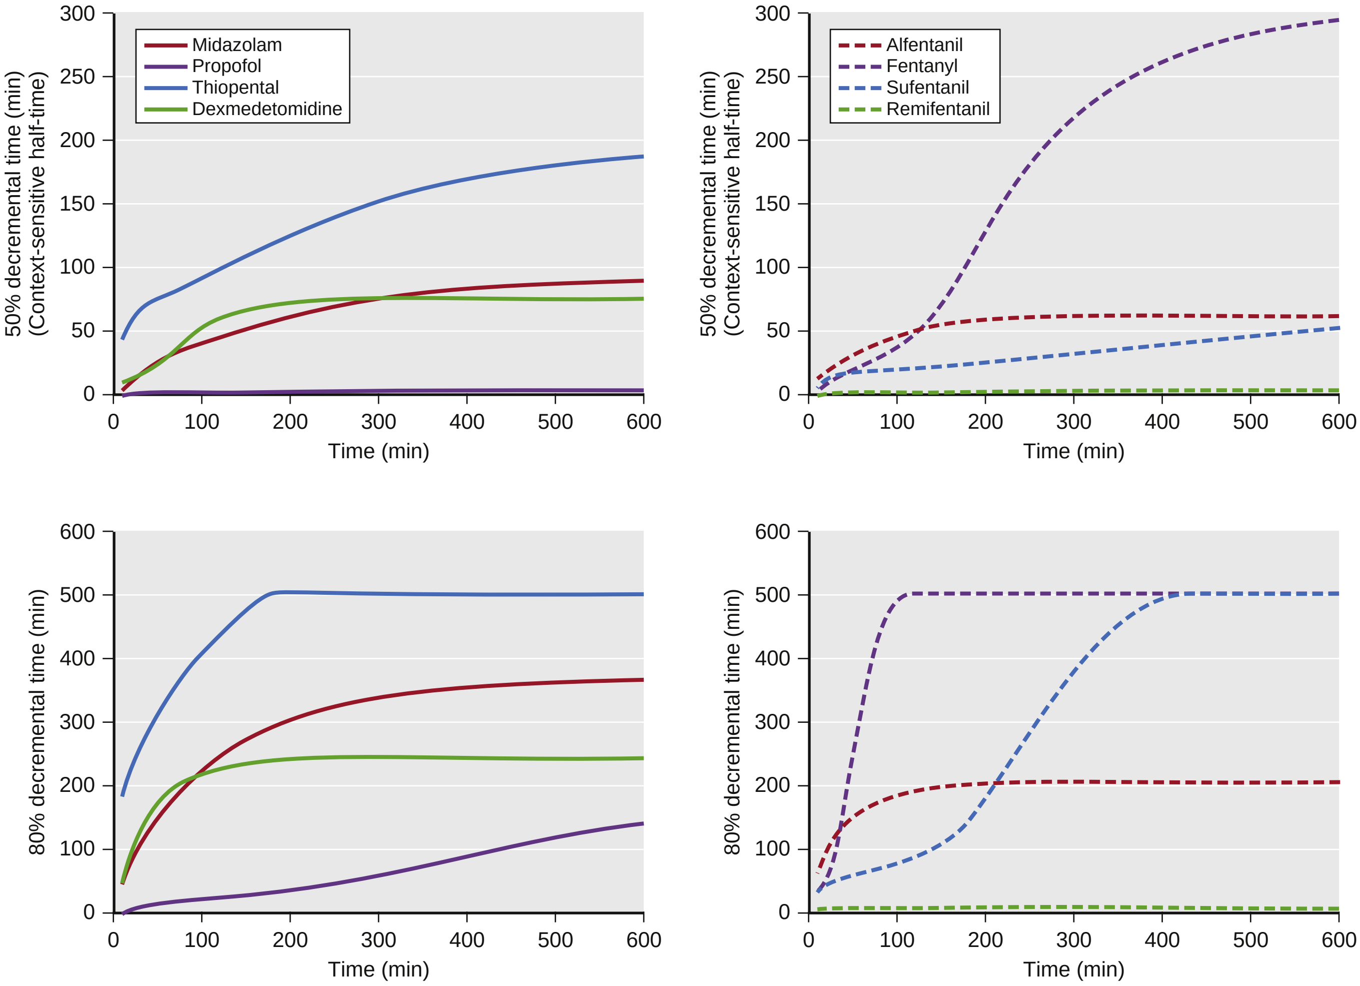

Fig. 18.16 Fifty percent and 80% decrement times for selected sedatives *(left side)* and opioids *(right side)*. The vertical axes refer to the time required to reach the desired decrement time. The horizontal axes refer to infusion duration. Simulations of the decrement times used published pharmacokinetic models for each sedative and analgesic. (Data from references 5, 43, 57, and 68-70.)

effect usually results in the phenomenon called hysteresis in which two different plasma concentrations correspond to one drug effect or one plasma concentration corresponds to two drug effects. Fig. 18.17 shows that different concentrations, C and c, correspond to the same bispectral index scale (BIS). To collapse the hysteresis between plasma concentration and effect and to match one plasma concentration to one drug effect, this lag is often modeled with an effect-site compartment added to the central compartment. Kinetic micro rate constants used to describe biophase include k_{1e} and k_{e0}. The k_{1e} describes drug movement from the central compartment to the effect site, and k_{e0} describe the elimination of drug from the effect-site compartment. There are two important assumptions with the effect-site compartment: (1) the amount of drug that moves from the central compartment to the effect-site compartment is negligible and vice versa, and (2) there is no "volume" estimate to the effect-site compartment.

Typically, the relationship between plasma and the site of drug effect is modeled with an "effect-site" compartment model, as shown in Fig. 18.18. The site of drug effect is connected to plasma by a first-order process. The equation that relates effect-site concentration to plasma concentration is

$$\frac{dCe}{dt} = k_{e0} \times (Cp - Ce) \qquad (18.20)$$

where Ce is the effect-site concentration, Cp is the plasma drug concentration, and k_{e0} is the rate constant for elimination of drug. The constant k_{e0} describes the rate of rise and offset of drug effect (Fig. 18.19).

In summary, although of interest to many clinicians, the conventional pharmacokinetic term *half-life* has limited meaning to anesthetic practice since the clinical behavior of drugs used in anesthesia is not well described by half-life. Instead, the pharmacokinetic principles discussed in this section (such as volume of distribution, clearance, elimination, front-end kinetics, back-end kinetics, context-sensitive half-time, and biophase) describe how drugs used in anesthesia will behave.

Pharmacodynamic Principles

Simply stated, pharmacokinetics describes what the body does to the drug, whereas pharmacodynamics describes what the drug does to the body. In particular, pharmacodynamics describes the relationship between drug concentration and pharmacologic effect.

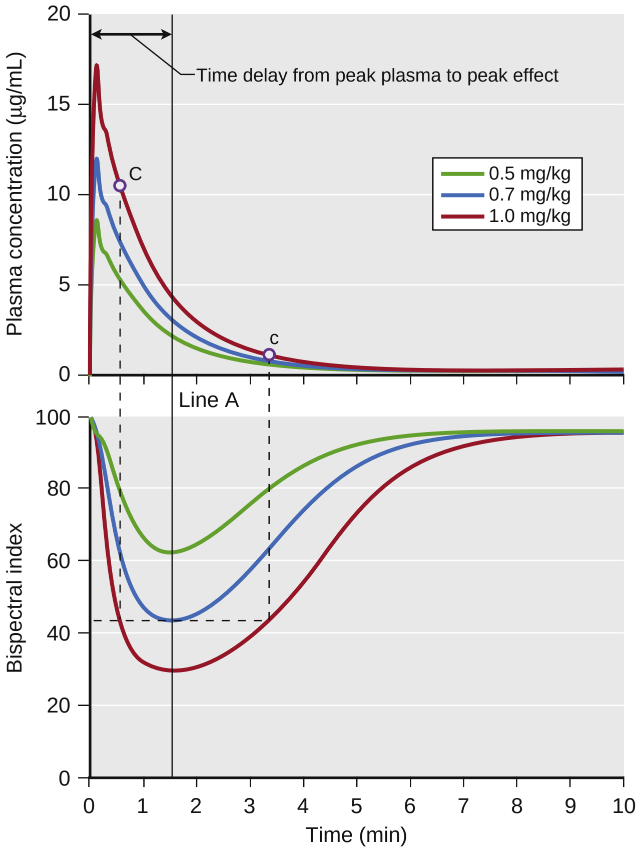

Fig. 18.17 Illustration of hysteresis. The top plot presents a simulation of three propofol doses and the resultant plasma concentrations. The bottom plot presents a simulation of the predicted effect on the bispectral index scale (BIS). These simulations assume linear kinetics: regardless of the dose, effects peak at the same time *(line A)* as do the plasma concentration. The time to peak effect is 1.5 minutes. Even the plasma concentrations of point *C* and *c* are different; the BIS of those two points are same. It shows the hysteresis between plasma concentration and BIS. Simulations used published pharmacokinetic and pharmacodynamic models. (Data from references 32 and 57.)

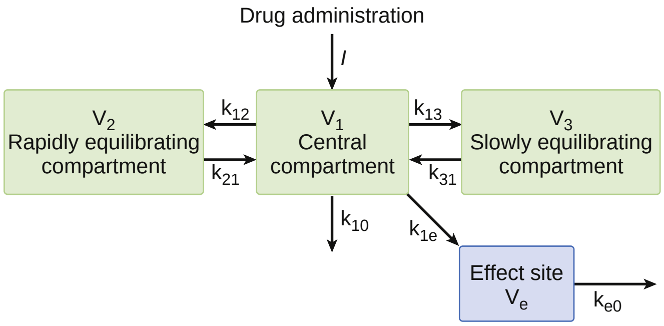

Fig. 18.18 A three-compartment model with an added effect site to account for the delay in equilibration between the rise and fall in arterial drug concentrations and the onset and offset of drug effect. The effect site is assumed to have a negligible volume.

Models used to describe the concentration-effect relationships are created in much the same way as pharmacokinetic models; they are based on observations and used to create a mathematical model. To create a pharmacodynamic model, plasma drug levels and a selected drug effect are measured

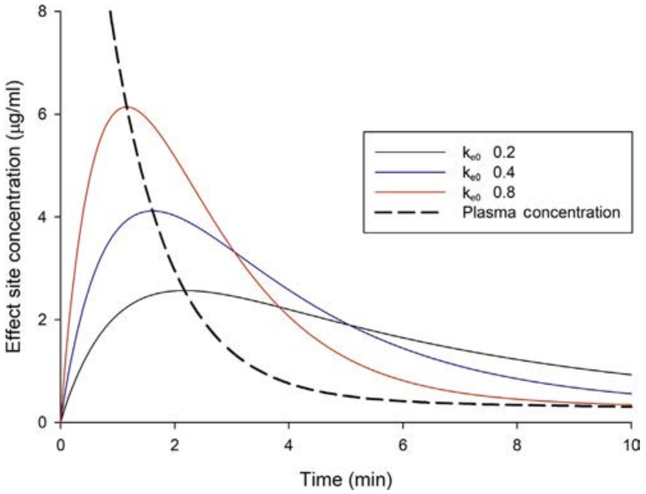

Fig. 18.19 Effect of the k_{e0} changes. As the k_{e0} decreases, the time to peak effect is prolonged. (Data from references 32, 57, 67.)

simultaneously. For example, consider the measured plasma concentrations of a drug following a bolus dose and the associated changes in the spectral edge from one individual presented in Fig. 18.20. Spectral edge is an easily captured metric used to quantify the electroencephalogram (EEG). Shortly after the plasma concentration peaks, the spectral edge starts to drop, reaches a nadir, and then returns to baseline as the plasma concentrations drop to near 0.

Combining data from several individuals and plotting the measured concentrations versus the observed effect (modified to be a percentage of the maximal effect across all individuals), the data create a hysteresis loop (Fig. 18.21). The ascending portion of the loop represents rising drug concentrations (see arrow). While rising, the increase in drug effect lags behind the increase in drug concentration. For the descending loop, the decrease in drug effect lags behind the decrease in drug concentration.

To create a pharmacodynamic model, the hysteresis loop is collapsed using modeling techniques that account for the lag time between plasma concentrations and the observed effect. These modeling techniques provide an estimate of the lag time, known as the $t_{1/2}k_{e0}$, and an estimate of the effect-site concentration (Ce) associated with a 50% probability of drug effect (C_{50}). Most concentration effect relationships in anesthesia are described with a sigmoid curve. The standard equation for this relationship is the “Hill Equation,” also known as the “sigmoid E_{max} relationship” (Eq. 18.21),

$$\text{Effect} = E_0 + \left(E_{max} - E_0\right) * \left(C^{g} / \left(C_{g}^{50} + C^{g}\right)\right) \qquad (18.21)$$

where E_0 is the baseline effect, E_{max} is the maximal effect, C is the drug concentration, and γ (gamma) represents the slope of the concentration-effect relationship. Gamma (γ) is also known as the “Hill coefficient.” For values of $\gamma < 1$, the curve is hyperbolic; for values of $\gamma > 1$, the curve is sigmoid. Fig. 18.22 presents an example of this relationship: a fentanyl effect-site concentration-effect curve for analgesia. This example illustrates how C_{50} and γ characterize the concentration-effect relationship.

Potency and Efficacy

Two important concepts are relevant to this relationship: potency and efficacy. Potency describes the amount of drug

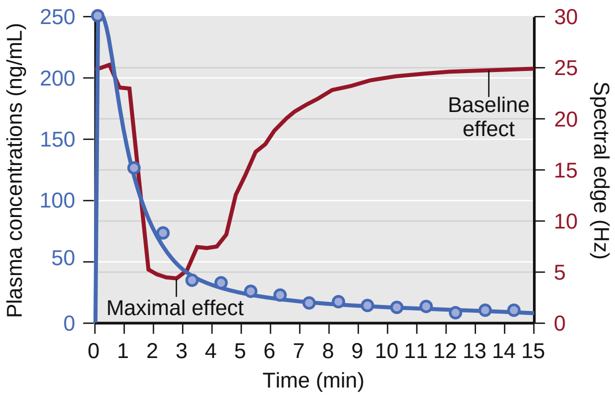

Fig. 18.20 Schematic representation of drug plasma concentrations *(blue circles)* following a bolus and the associated changes in the electroencephalogram's spectral edge *(red line)* measured in one individual. Note that changes in spectral edge lag behind changes in plasma concentrations.

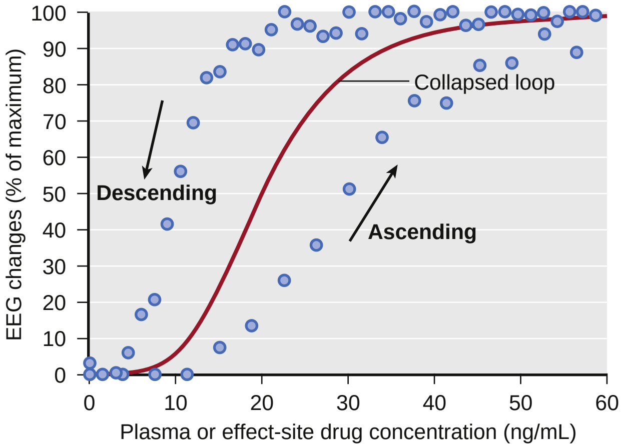

Fig.18.21 Schematic representation of plasma concentrations versus normalized spectral edge measurements (presented as a percentage of maximal effect) from several individuals *(blue circles)*. The black arrows indicate the ascending and descending arms of a hysteresis loop that coincide with increasing and decreasing drug concentrations. The red line represents the pharmacodynamic model developed from collapsing the hysteresis loop. *EEG*, Electroencephalogram.

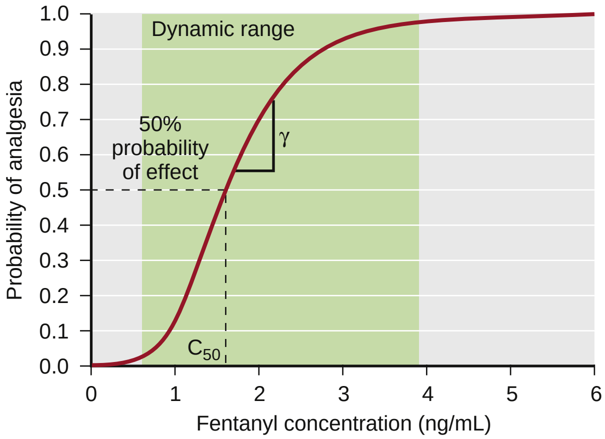

Fig.18.22 A pharmacodynamic model for the analgesic effect of fentanyl. The green area represents the dynamic range, the concentration range where changes in concentration lead to a change in effect. Concentrations above or below the dynamic range do lead to changes in drug effect. The C_{50} represents the concentration associate with 50% probability of analgesia. Gamma (γ) represents the slope of the curve in the dynamic range.

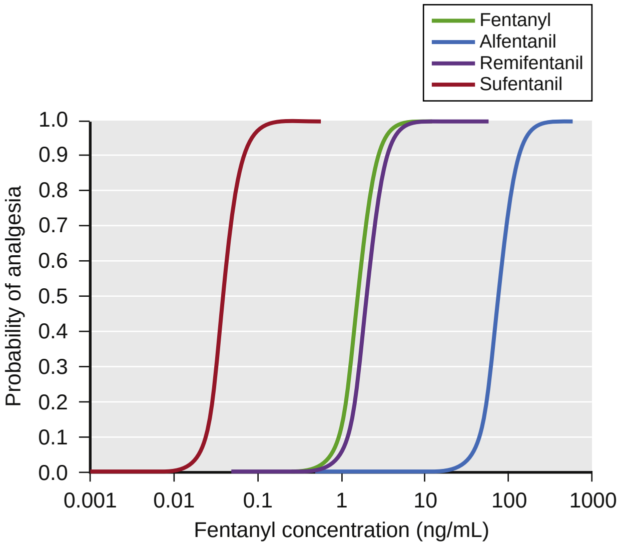

Fig. 18.23 Pharmacodynamic models for fentanyl congeners. The C_{50} for each drug is different, but the slope and maximal effect are similar. (From Egan TD, Muir KT, Hermann DJ, et al. The electroencephalogram (EEG) and clinical measures of opioid potency: defining the EEG-clinical potency relationship ("fingerprint") with application to remifentanil. *Int J Pharmaceut Med.* 2001;15(1):11–19.)

required to elicit an effect. The C_{50} is a common parameter used to describe potency. For drugs that have a concentration-versus-effect relationship that is shifted to the left (small C_{50}), the drug is considered to be more potent; the reverse is true for drugs that have a concentration-versus-effect relationship shifted to the right. For example, as illustrated in Fig. 18.23, the analgesia C_{50} for some of the fentanyl congeners ranges from small for sufentanil (0.04 ng/mL) to large for alfentanil (75 ng/mL). Thus, sufentanil is more potent than alfentanil.

Efficacy is a measure of drug effectiveness at producing an effect once it occupies a receptor. Similar drugs that work through the same receptor may have varying degrees of effect despite having the same receptor occupancy. For example, with G-protein coupled receptors, some drugs may bind the receptor in such a way as to produce a more pronounced activation of second messengers causing more of an effect than others. Drugs that achieve maximal effect are known as full agonists, and those that have an effect less than maximal effect are known as partial agonists.

Effective Versus Lethal Doses

A single drug can have multiple effects. The C_{50} concept is used to compare various drug effects for a single drug. For example, as illustrated in Fig. 18.24, fentanyl has a different C_{50} for analgesia (2 ng/mL), ventilatory depression (4 ng/mL), loss of response to laryngoscopy (15 ng/mL), and changes in the EEG (20 ng/mL).[6]

The concentration range where changes in drug effect occur is known as the *dynamic range*. In Fig. 18.22, the

The electroencephalogram (EEG) and clinical measures of opioid potency: defining the EEG-clinical potency relationship ("fingerprint") with application to remifentanil. *Int J Pharmaceut Med.* 2001;15(1):11–19.)

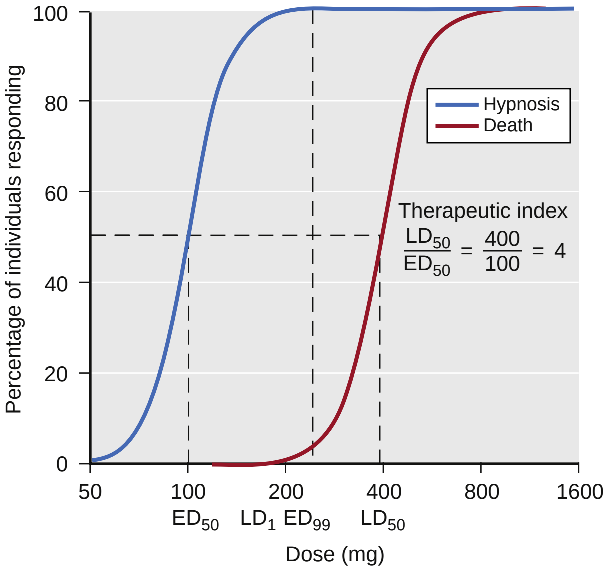

Fig. 18.25 Median effective dose (ED_{50}), median lethal dose (LD_{50}), and the therapeutic index. The blue curve represents the dose-effect relationship for a sedative hypnotic to achieve unresponsiveness. The red curve represents the dose-effect relationship for the same sedative hypnotic to achieve death. The therapeutic index is the ratio of the LD_{50}/ED_{50}, which in this example is 400. Also of interest are the ED_{99} and LD_1. The ED_{99} is the dose with a 99% probability of unresponsiveness, and the LD_1 is the dose with a 1% probability of death. In this example, the LD_1 is less than the ED_{99}, which is clinically unacceptable.

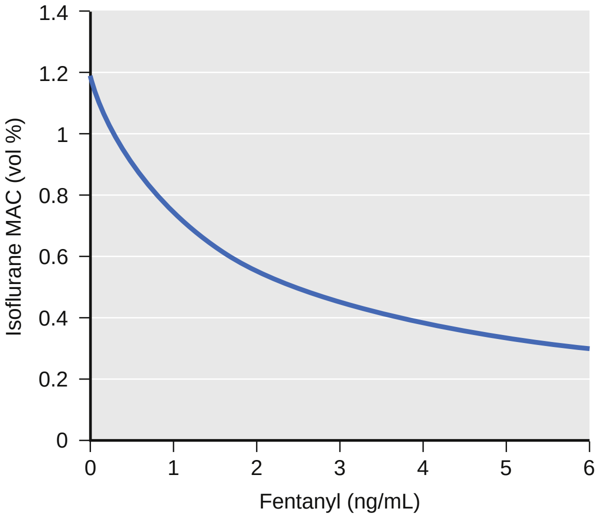

Fig. 18.26 The influence of fentanyl on the isoflurane minimal alveolar concentration *(MAC)* associated with a 50% probability of movement with skin incision. (Modified from McEwan AI, Smith C, Dyar O. Isoflurane minimum alveolar concentration reduction by fentanyl. *Anesthesiology.* 1993;78:864–869.)

dynamic range is from 0.6 to 3.9 ng/mL to cover a probability of analgesia ranging from 2% to 97%. Concentrations outside the dynamic range do not yield much change in drug effect. Levels below the dynamic range are ineffective, and those above the dynamic range do not provide additional effect.

Like other effects, the concentration-relationship for death is also described with a sigmoid E_{max} curve. The relationship between drug and effect is expressed differently in that the horizontal axis uses dose in place of concentration. Similar to the C_{50}, the ED_{50} is the dose at which there is a 50% probability of effect, and the LD_{50} is the dose with a 50% probability of death. The therapeutic index of a drug is defined as the ratio between the LD_{50} and the ED_{50} (Fig. 18.25). The larger the ratio, the safer the drug is for clinical use.

Anesthetic Drug Interactions

Anesthetics rarely consist of one drug, but rather a combination of drugs to achieve desired levels of hypnosis, analgesia, and muscle relaxation. Hypnotics, analgesics, and muscle relaxants all interact with one another such that rarely does one drug, when administered in the presence of other drugs, behave as if it were administered alone. For example, when administering an analgesic in the presence of a hypnotic, analgesia is more profound with the hypnotic than by itself and hypnosis is more profound with the analgesic than by itself. Thus, anesthesia is the practice of applied drug interactions. This phenomenon is likely a function of each class of drug exerting an effect on different receptors.

Early work by McEwan and associates described interactions between two drugs and is illustrated in Fig. 18.26.[7] It presents the interaction between isoflurane, a likely GABA agonist, and fentanyl, an opioid receptor agonist. This plot illustrates two key points: First, with a relatively low fentanyl concentration (<2 ng/mL), there is a substantial decrease (>50%) in the end tidal isoflurane concentration necessary to achieve minimal alveolar concentration (MAC) necessary to avoid movement with skin incision. Second, with fentanyl concentrations above 3 ng/mL, the end tidal concentration of isoflurane to maintain the MAC, although low, does not change much. Thus, there is a ceiling effect indicating that some isoflurane is necessary regardless of the fentanyl concentration to maintain a MAC of anesthesia.

A substantial body of work has been done to explore how anesthetic drugs interact with one another. As illustrated in Fig. 18.27, interactions have been characterized as antagonistic, additive, and synergistic. When drugs that have an

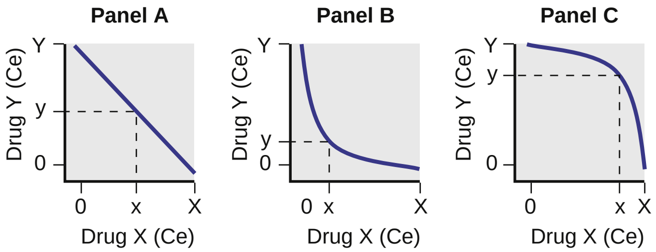

Fig. 18.27 Drug interactions. For two drugs, X and Y, Panel (A) represents additive, Panel (B) represents synergistic, and Panel (C) represents antagonistic interactions.

additive interaction are coadministered, their overall effect is the sum of the two individual effects. With antagonistic interactions, the overall effect is less than if the drug combination were additive; with synergistic interactions, the overall effect is greater than if the drug combination were additive.

A term used to characterize the continuum of drug concentrations across various combinations of drug pairs (X in combination with Y) is the isobole. The isobole is an isoeffect line for a selected probability of effect. A common isobole is the 50% isobole line. It represents all possible combinations of two-drug effect-site concentrations that would lead to a 50% probability of a given effect. Other isoboles are of more clinical interest. For example, the 95% isobole for loss of responsiveness represents the concentration pairs necessary to ensure a 95% probability of unresponsiveness. Similarly, the 5% isobole represents the concentration pairs in which the likelihood of that effect is low (i.e., most patients would be responsive). When formulating an anesthetic dosing regimen, dosing an anesthetic to achieve a probability of effect just above but not far beyond the 95% isobole is ideal (Fig. 18.28).

Hendrickx and colleagues surveyed the literature for work in both humans and animal models that described anesthetic drug interactions for opioids, sedative hypnotics, and inhalation agents for two anesthetic effects: (1) loss of responsiveness (humans) and loss of the righting reflex (animals) and (2) immobility defined as loss of movement in response to noxious stimulus in a nonparalyzed subject.[8] They found several interesting features of anesthetic drug combinations. First, inhalation agents when combined are strictly additive, suggesting a common mechanism of action, except for nitrous oxide, which has an infra-additive interaction with other inhalation agents. Second, interactions between various intravenous drugs and inhalation agents are synergistic except for nitrous oxide and GABA sedative hypnotics. Third, interactions between different classes of intravenous drugs (e.g., opioids and sedative hypnotics) are also primarily synergistic, except for ketamine and benzodiazepines (Fig. 18.29).

Several researchers have developed mathematical models that characterize anesthetic drug interactions in three dimensions. These models are known as response surface models and include effect-site concentrations for each drug, as well as a probability estimate of the overall effect. Fig. 18.30 presents the propofol–remifentanil interaction for loss of responsiveness as published by Bouillon and associates.[9] The response surface presents the full range of remifentanil-propofol isoboles (0%-100%) for loss of responsiveness. There are two common representations of the response surface model: the three-dimensional plot and the topographical plot. The topographical plot represents a top-down view of the response surface with drug concentrations on the vertical and horizontal axes. Drug effect is represented with selected isobole lines (i.e., 5%, 50%, and 95%).

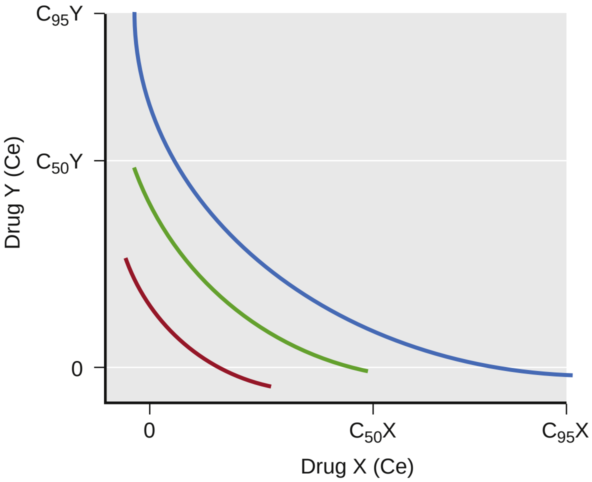

Fig. 18.28 Schematic illustration of iso-effect (isobole) lines. The red, green, and blue lines represent the 50% and 95% isoboles for a synergistic interaction between drugs X and Y. Isoboles represent concentration pairs with an equivalent effect. A set of 5%, 50%, and 95% isoboles can be used to describe the dynamic range of the concentrations for drugs X and Y for a given effect. As with single concentration effect curves, the ideal dosing leads to concentration pairs that are near the 95% isobole.

Response surface models have been developed for a variety of anesthetic effects to include responses to verbal and tactile stimuli, painful stimuli, hemodynamic or respiratory effects, and changes in electrical brain activity. For example, with airway instrumentation, response surface models have been developed for loss of response to placing a laryngeal mask airway,[10] laryngoscopy,[11,12] tracheal intubation,[13] and esophageal instrumentation[14] for selected combinations of anesthetic drugs. Although many response surface models exist, there are several gaps in available models covering all common combinations of anesthetic drugs and various forms of stimuli encountered in the perioperative environment.

Recent work characterizing the interaction between sevoflurane and remifentanil has been done for a variety of drug effects to include loss of responsiveness, loss of response to several surrogates of surgical pain such as electrical tetany (up to 50 mA), pressure algometry (50 PSI pressure on the anterior tibial), loss of response to laryngoscopy, and temperature.[12] Using end tidal measures of sevoflurane was found to be inaccurate under non-steady state conditions (i.e., with a change in vaporizer settings). This was because end tidal concentrations did not account for the hysteresis (or time lag) between end tidal and effect-site concentrations. Improved model predictions were achieved when using estimated effect site concentrations.[15] Overall, for sevoflurane-opioid interactions, analgesic effects are

Fig. 18.29 Summary of drug interactions in humans and animals for hypnosis (loss of responsiveness in humans, loss of righting reflex in animals) and immobility (loss of movement in response to a noxious stimulus). The numbers in each cell refer to the number of papers supporting the finding. α_2 Agonists include dexmedetomidine and clonidine. Opioid agonists include morphine, remifentanil, fentanyl, sufentanil, and alfentanil. Dopamine agonists include droperidol and metoclopramide. Na^+ (sodium) channel antagonists include lidocaine and bupivacaine. The letter "a" indicates the interaction was characterized in an animal model. The thick diagonal line separates studies characterizing drug-drug interactions of hypnosis *(bottom half)* and immobility *(top half)*. *GABA*, Gamma aminobutyric acid (GABA agonist drugs include propofol, thiopental, methohexital, and etomidate; $GABA_{BDZ}$ agonist drugs that work via benzodiazepine binding site include midazolam and diazepam); *NMDA*, N-methyl-D-aspartate (NMDA receptor antagonists include ketamine) (From Hendrickx J, Eger EI 2nd, Sonner JM, et al. Is synergy the rule? A review of anesthetic interactions producing hypnosis and immobility. *Anesth Analg*. 2008;107:494–506.)

markedly synergistic whereas sedative effects are somewhat synergistic.

Preliminary work has explored the adaptability of the sevoflurane-remifentanil interactions to other potent inhaled agent–opioid combinations using MAC and opioid equivalencies.[16] Predictions from sevoflurane-remifentanil models adapted to isoflurane-fentanyl correlated well with observed effects in patients undergoing elective general surgery procedures. Recent work has also explored the construction of models that characterize the interactions between three or more drugs.[17] For example, Vereecke and associates published a model that accounts for nitrous oxide, sevoflurane, and remifentanil.[18] This is of clinical relevance because most anesthetics consist of more than two anesthetic drugs.

Substantial work has explored interactions between sedative hypnotics and opioids, primarily propofol with alfentanil[19] or remifentanil[9,11,14,20,21] for a variety of effects. As with potent inhaled anesthetics and opioids, the interactions between sedative hypnotics and opioids for analgesic effects are markedly synergistic whereas sedative hypnotic effects are somewhat synergistic.

Some work has explored interactions between different types of sedative hypnotics. Two include midazolam combined with propofol[22,23] and propofol combined with a volatile anesthetic.[24–26] These interactions were found to be primarily additive.

Drug Displays

One major disadvantage to response surface models, as presented in the literature, is that they are complex and difficult to use in a clinical setting. Recent work has adapted these models to drug displays that allow clinicians to use them in real-time patient care settings.

These displays provide estimates of not only drug concentrations (both plasma and effect site) but various drug effects over time such as loss of responsiveness, analgesia, and reduction in response to peripheral train-of-four simulation (i.e., monitoring of muscle relaxant action), among others. With manual entry of patient demographics (age, gender, height, and weight) and drugs administered by syringe, either by bolus or continuous infusion along with automated data collection from an anesthesia machine (end tidal potent inhaled anesthetic concentrations and, in some instances, infusion pump information), drug displays provide predictions of drug concentration and effects. Drug displays are currently available from several anesthesia machine manufacturers (Navigator Suite from GE Healthcare, Wauwatosa, Wisconsin, USA, and SmartPilot View from Dräger, Lübeck, Germany). An example of a drug display is presented in Fig. 18.30. All drug display examples are based on response surface interaction models.

A unique feature of drug displays is that a given dosing regimen can be simulated prior to administration. This information may be useful in identifying the optimal dose in challenging patients, especially when more than one

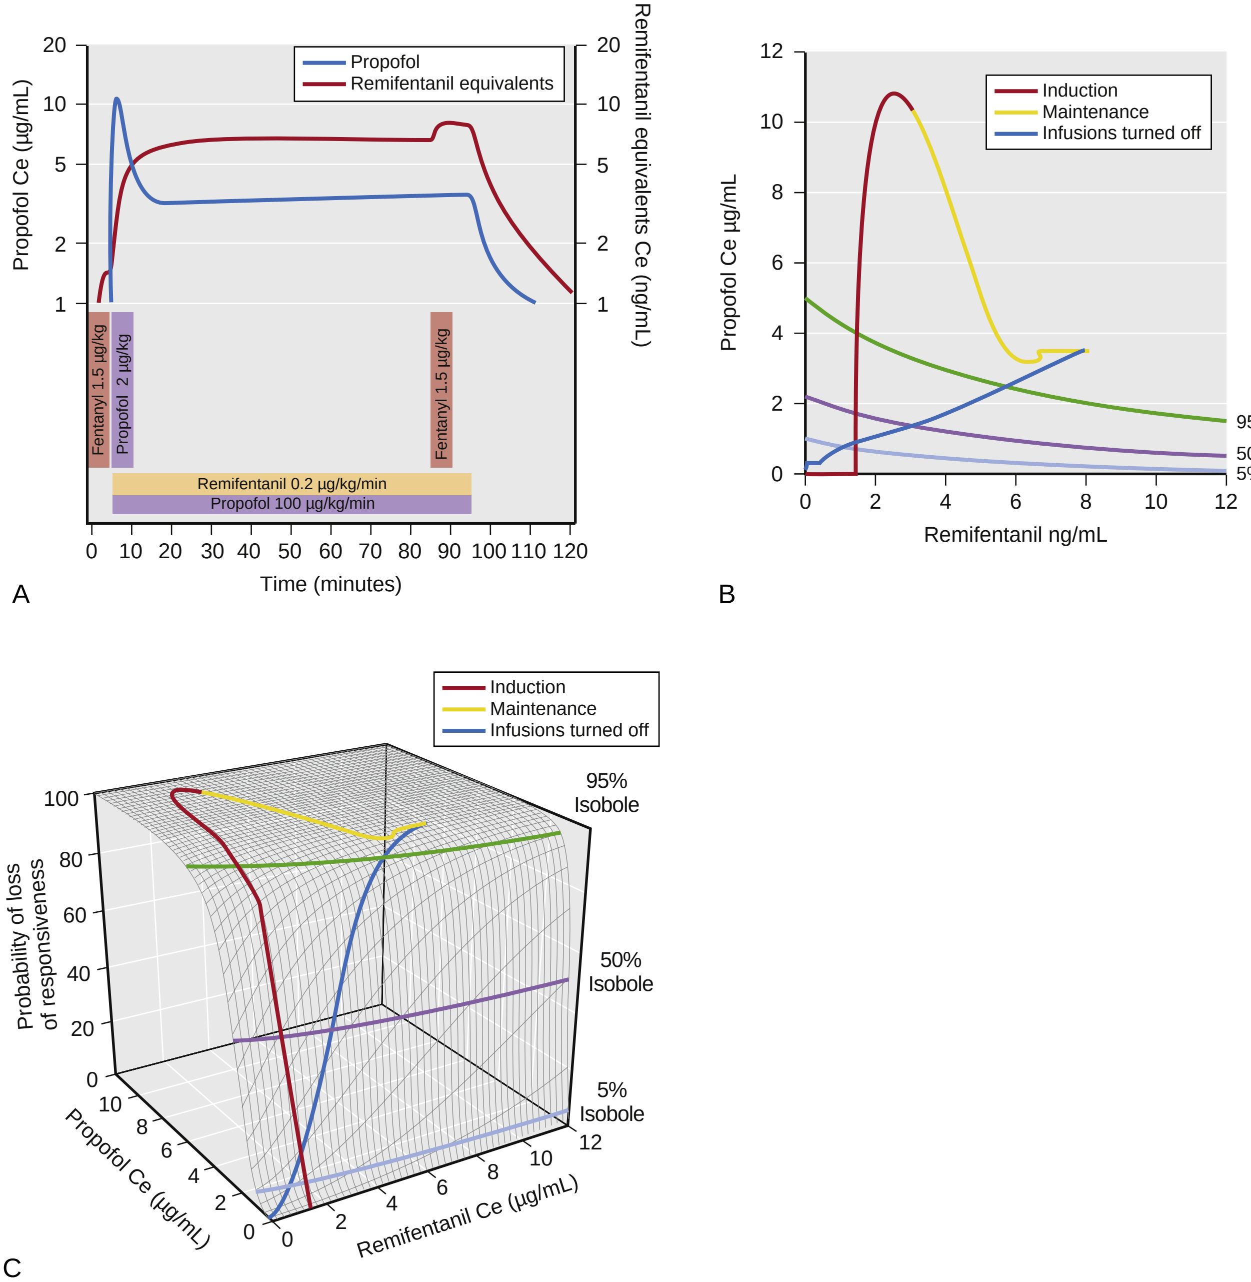

Fig. 18.30 (A–C) Simulation of a 90-minute total intravenous anesthetic consisting of propofol bolus (2 μg/kg) and infusion (100 μg/kg/min), remifentanil (0.2 μg/kg/min), and intermittent fentanyl boluses (1.5 μg/kg). (A) Resultant effect site concentrations (Ce) are presented. (B) Predictions of loss of responsiveness are presented on a topographical *(top-down)* view. (C) A three-dimensional response surface is shown. The light blue, purple, and green lines represent the 5%, 50%, and 95% isoboles. Each isobole presents the propofol-remifentanil pairs that yield the same effect. The inward bow of the isoboles indicates that the interaction is synergistic. The isoboles are in close proximity to one another indicating a steep transition from responsive to unresponsive.

drug is used. The drug displays use population models that, although generalizable, may not provide a good "fit" to every patient. For some drug display systems, observed patient responses are used to calibrate predictions of drug effect (Fig. 18.31). For example, with elderly or debilitated patients, smaller doses are often required to achieve a desired effect. Drug displays allow clinicians to identify concentrations that produce a desired response and can be used to titrate additional anesthetic.

There are several other advantages from using drug displays. When titrating an anesthetic, it is often difficult to appreciate when effect-site concentrations are near steady state. Clinicians may be tempted to administer additional drug assuming that drug concentrations have peaked (with bolus dosing) or are near steady-state conditions (with continuous infusions of potent inhaled anesthetics). Clinicians may also be impatient, assuming that drug concentrations are near zero when in fact they are still increased, even after terminating delivery (e.g., the end tidal potent inhaled agent concentration is 0 mm Hg but there is persistent unresponsiveness).

A second advantage is that drug displays provide a means of delivering passive TCI. Although widely used throughout the world, TCI is not used in the United States because of regulatory barriers.[27] TCI uses population pharmacokinetic models to drive infusion pumps. After entering the target plasma or effect-site concentration, a computer identifies the optimal infusion rate to achieve that concentration. With passive TCI, population models are used to display predicted effect-site concentrations and associated effects over time, but the models do not deliver information to drive infusion pumps as with TCI. With this approach,

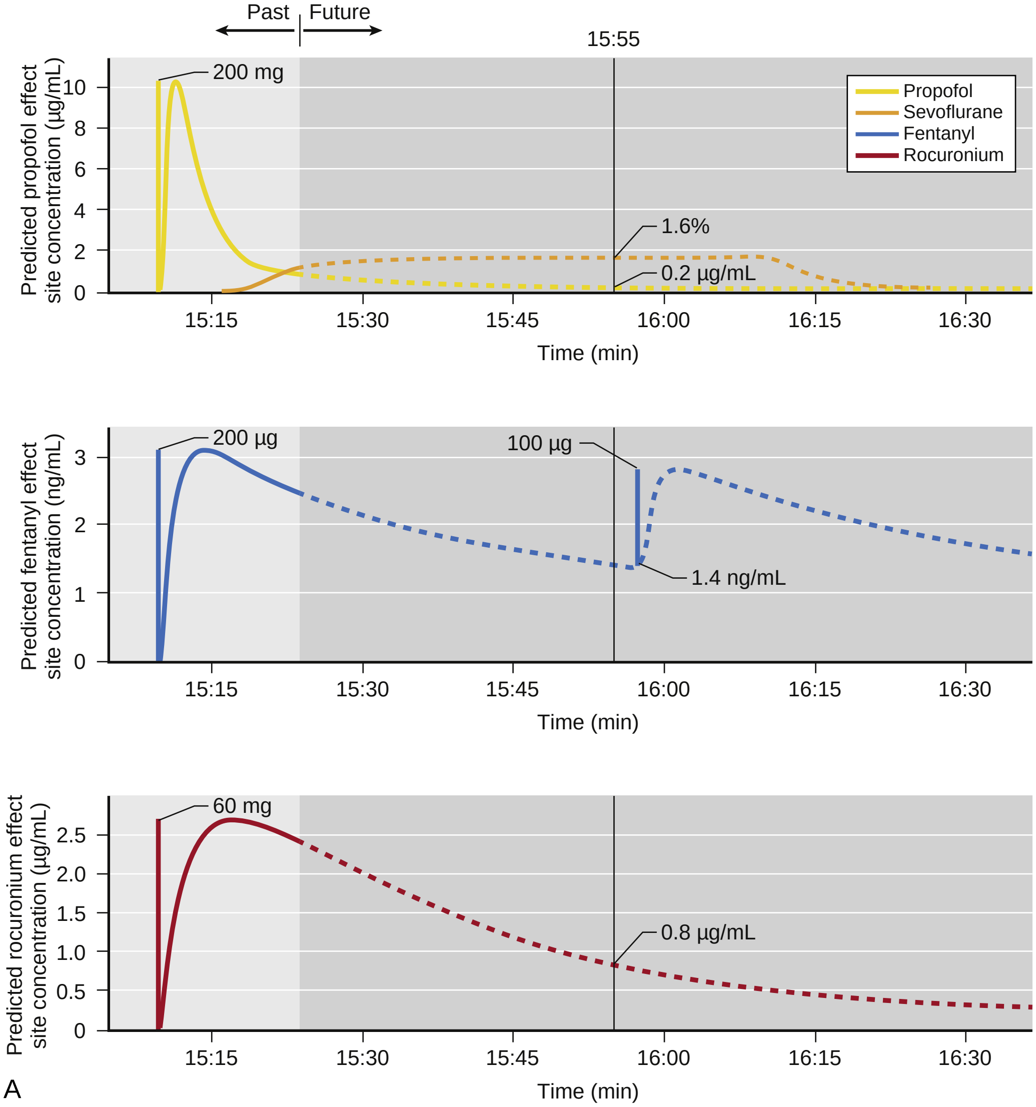

Fig. 18.31 (A) Example of a drug display. This example presents predictions of site effect concentrations (A) and drug effects (B) for a combined technique using fentanyl (2 µg/kg), propofol (2 mg/kg), and rocuronium (0.6 mg/kg) boluses and maintenance with sevoflurane (2%) and fentanyl bolus (1 µg/kg). This simulation assumes a 30-year-old, 100-kg male, 183 cm tall, with normal cardiac output and lung ventilation. (A) Predicted effect site concentrations for propofol *(bright yellow line)*, sevoflurane *(dark orange line)*, fentanyl *(blue line)*, and rocuronium *(red line)*. Bolus doses are represented as vertical lines, with the dose labeled adjacent to the line. Past predictions are solid lines and future predictions are dashed lines. The vertical black line represents a future prediction of effect site concentrations at 15:55 PM. Concentrations are reported.

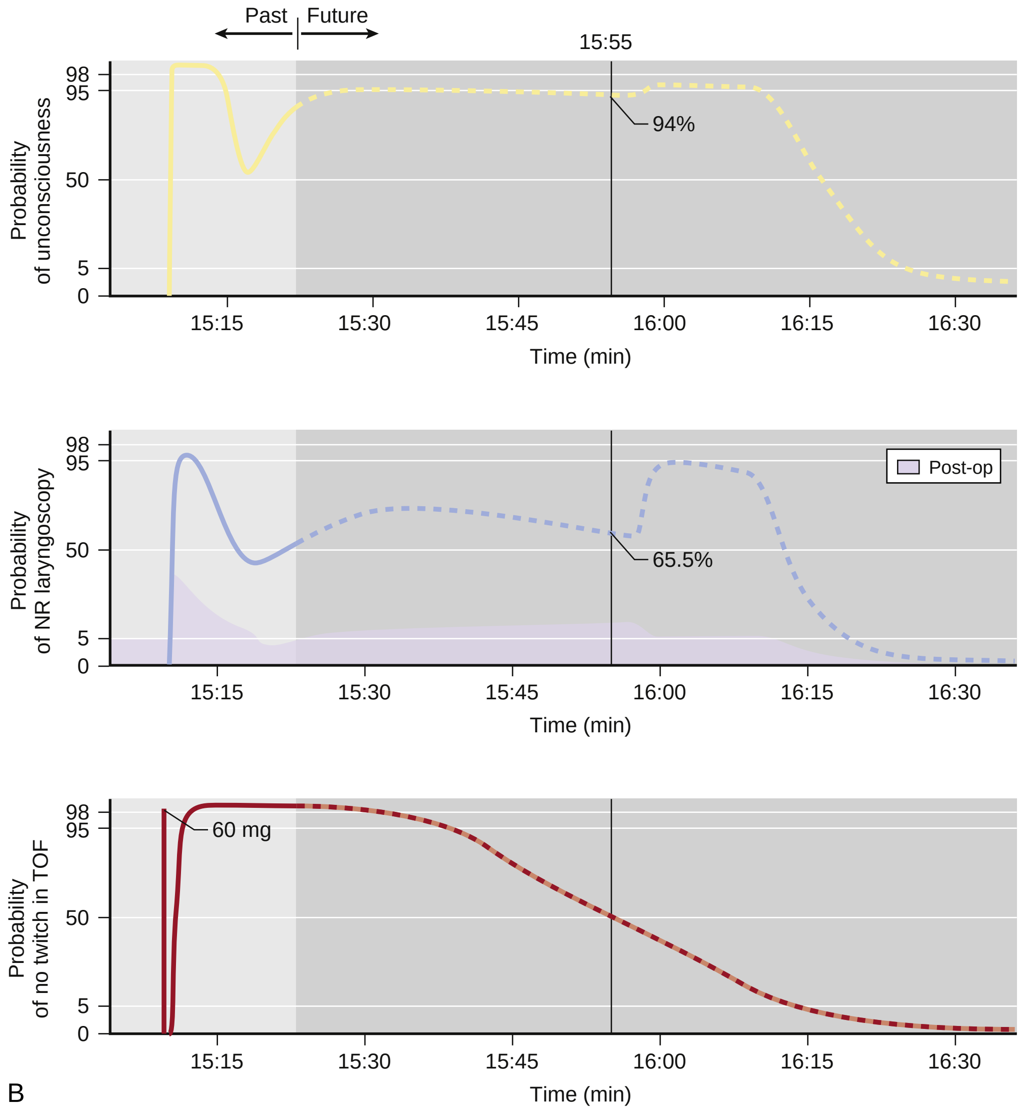

Fig. 18.31 Cont'd (B) Predicted drug effects. Probability of unresponsiveness *(yellow line)*, probability of no response to laryngoscopy *(blue line)*, and probability of loss of train-of-four *(red line)* from this combined technique. The white horizontal lines represent the 5%, 50%, 95%, and 98% probability of effect. The vertical black line represents a future prediction of drug effects at 15:55 PM. *NR*, No response to laryngoscopy; *TOF*, train-of-four. ([A] From Applied Medical Visualizations, Salt Lake City, Utah.)

clinicians can test out dosing regimens (bolus doses and infusion rates) before administering them to confirm they will achieve a desired effect. These features provide for a more consistent approach to drug delivery.

A third advantage is that they provide a better approach to dosing anesthetics. Instead of considering an anesthetic in terms of MAC, where 50% of patients may respond to surgical stimulus, drug displays provide a more refined characterization of anesthetic effect. Clinicians do not titrate an anesthetic to achieve a 50% probability of effect but rather aim for a 95% to 99% probability of effect. With response surfaces, anesthetic dosing regimens necessary to achieve this level of effect are easily visualized. Second, the concept of MAC does not fully embody the three elements of an anesthetic: analgesia, sedation and hypnosis, and muscle relaxation. Drug displays provide a means of visualizing all three effects simultaneously over a full 0% to 100% probability range.

Special Populations

When formulating an anesthetic, many aspects of patient demographics and medical history need to be considered to find the correct *dose*: age; body habitus; gender; chronic exposure to opioids, benzodiazepines, or alcohol; the presence of heart, lung, kidney, or liver disease; and the extent of blood loss or dehydration. Any of these factors can dramatically affect anesthetic drug kinetics and dynamics. Unfortunately, most studies characterizing anesthetic drug behavior have been conducted in healthy volunteers that rarely represent the general population presenting for surgery. Extensive work has explored how some patient characteristics (e.g., obesity) influence anesthetic drug behavior, whereas other patient characteristics remain difficult to assess (chronic opioid exposure). In addition, not all anesthetics have been studied. Most work has primarily focused on newer anesthetic drugs, such as propofol and remifentanil. This section will briefly summarize work that has been done to characterize the pharmacokinetics and pharmacodynamics in a few unique special populations.

Influence of Obesity on Anesthetic Drugs

Obesity is a worldwide epidemic, and overweight patients frequently undergo anesthesia and surgery. Furthermore, pharmacologic alterations of anesthetics occur in obese individuals. In general, manufacturer dosing recommendations are on a per-kg basis according to the actual total body weight (TBW). Anesthesia providers rarely use mg/kg dosing in obese patients for fear of administering an excessive dose (e.g., a 136-kg patient does not require twice as much drug as a patient of the same height who weighs 68 kg). To resolve this problem, several weight scalars were developed to avoid excessive dosing or under dosing in this patient population. Some of these include lean body mass (LBM), ideal body weight (IBW), corrected body weight (CBW), and fat-free mass (FFM). Table 18.1 presents the formulas used to estimate these weight scalars. Table 18.2 shows samples of the resultant scaled weight for lean and obese individuals. In general, the aim of weight scalars is to match dosing regimens for obese patients with what is required for normal-size patients. These scaled weights are usually smaller than TBW in obese patients and thus help prevent excessive drug dosing (Fig. 18.32). Scaled weights have been used in place of TBW for both bolus (mg/kg) and infusion (mg/kg/hr) dosing and also for TCI.

This section will discuss the pharmacologic (primarily pharmacokinetic) alterations of select intravenous anesthetic drugs (propofol, remifentanil, and fentanyl) in obese patients, review examples of weight scalars and their shortcomings when used in bolus and continuous infusion dosing, and when data are available, briefly describe pharmacologic models used to drive TCI.

Propofol

Dosing propofol in obese patients can be a challenge. For bolus dosing and continuous infusions, the choice of weight scalar is specific to the dosing technique being used (i.e., one is best for bolus dosing and another for continuous infusions). Furthermore, of the available propofol pharmacokinetic models, the one built from observations in obese patients may be best for TCI.

The influence of obesity on propofol pharmacokinetics is not entirely clear. Generally, in obese patients, the blood distributes more to nonadipose than to adipose tissues. This may result in higher plasma drug concentrations in obese patients with mg/kg dosing than in normal patients with less adipose mass. Furthermore, propofol clearance increases because of the increased liver volume and/or liver blood flow associated with obesity (and increased cardiac output). Distribution likely influences concentration peaks with bolus dosing, and clearance likely influences concentrations during and following infusions.

TABLE 18.1 Common Weight Scalars (Modified Added Modified Fat-Free Mass)

Name	Equations
Ideal body weight	Male: 50 kg + 2.3 kg for each 2.54 cm (1 inch) over 152 cm (5 ft) Female: 45.5 kg + 2.3 kg for each 2.54 cm (1 inch) over 152 cm (5 ft)
Corrected body weight	IBW + 0.4 × (TBW–IBW)
Lean body mass	Male: $1.1 \times TBW - 128 \times (TBW/Ht)^2$ Female: $1.07 \times TBW - 148 \times (TBW/Ht)^2$
Fat-free mass[66]	Male: $(9.27 \times 10^3 \times TBW)/(6.68 \times 10^3 + 216 \times BMI)$ Female: $(9.27 \times 10^3 \times TBW)/(8.78 \times 10^3 + 244 \times BMI)$
Pharmacokinetic mass[46,47]	$52/[1+(196.4 \cdot e^{-0.025\ TBW} - 53.66)/100]$ (fentanyl only)
Modified fat-free mass[28,36]	FFM + 0.4 × (TBW–FFM)

BMI, Body mass index (kg/m^2).

Dosing Scalars for Propofol. Simulations of an infusion using various weight scalars are presented in Fig. 18.33. The simulations predict propofol effect-site concentrations from a 60-minute infusion (167 μg/kg/min) in 176-cm (6-ft) males, obese (185 kg), and lean (68 kg). If dosed according to TBW, peak effect-site concentrations in a lean and obese individual are different; their respective peak propofol concentrations are approximately 5.2 and 7.1 μg/mL, respectively. If the obese individual is dosed to CBW, the peak concentration is near 4.5 μg/mL. The other weight scalars lead to much lower concentrations with the infusion.

Of the many available dosing scalars, authors recommend LBM[12] for bolus dosing (i.e., during induction) and TBW or CBW for infusions.[9,13] For continuous infusions, other weight scalars are likely inadequate (the most worrisome is LBM). When dosing to CBW, plasma concentrations may be lower than concentrations when dosed to TBW.

One concern with using TBW to dose continuous infusions is drug accumulation. Prior work, however, does not support this assumption. Servin and colleagues[28] performed pharmacokinetic analyses of propofol administration to normal and obese patients using TBW and CBW. The CBW was defined as the IBW + 0.4 × (TBW−IBW).[29] They found similar concentrations at eye opening in both groups

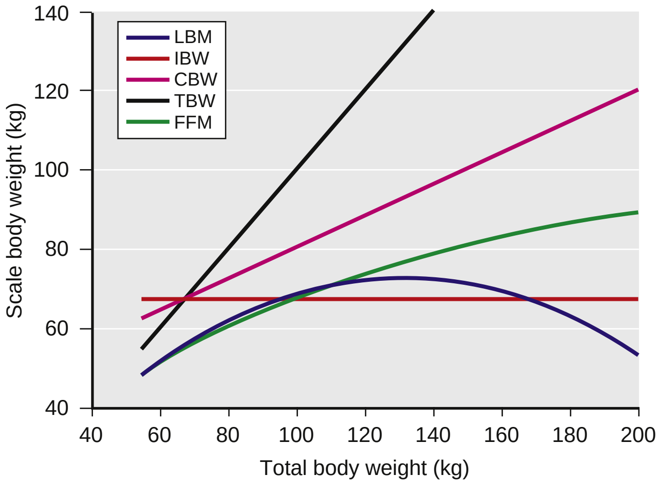

Fig. 18.32 Scaled weights as a function of total body weight *(TBW)*. Key points in this plot: IBW remains the same regardless of the TBW, and LBM starts to decline for weight increases above 127 kg. *CBW*, Corrected body weight; *FFM*, fat-free mass; *IBW*, Ideal body weight; *LBM*, lean body mass (for a 40-year-old male, 176 cm tall).

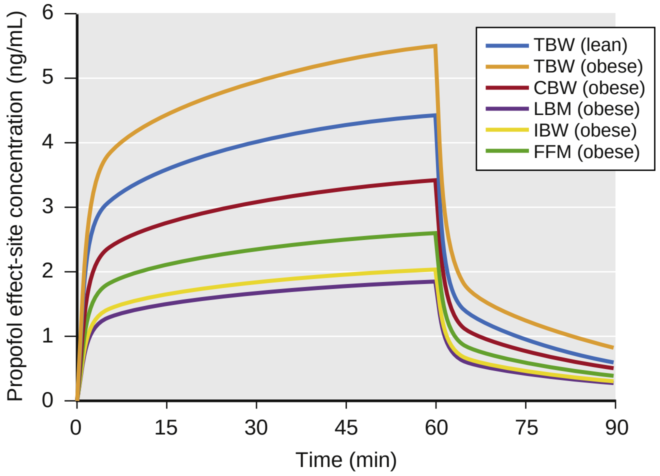

Fig. 18.33 Simulations of propofol effect site concentrations that result from a 60-minute infusion (10 mg/kg/h–167 μg/kg/min) to a 40-year-old male who is 176 cm tall. Simulations include the following dosing weights: total body weights *(TBW)* of 68 kg and 185 kg (body mass indices of 22 and 60, respectively) and scaled weights for the 185 kg weight to include Servin's corrected body weight *(CBW)*, lean body mass *(LBM)*, ideal body weight *(IBW)*, and fat-free mass *(FFM)*. Key points: At the 185-kg weight, when dosed to TBW, the infusion leads to high propofol concentrations, whereas when dosed to IBW or LBM, the infusion leads to low propofol concentrations. When the 185-kg individual is dosed using CBW, it best approximates the propofol concentrations that result from TBW in a lean individual. Predictions of propofol effect site concentrations were made using the Eleveld model.

and absence of propofol accumulation in obese patients; in fact, obese patients showed earlier awareness after the termination of propofol infusions than did the normal subjects. Data suggest that dosing infusions according to Servin's CBW may underdose obese patients.[30]

Propofol Kinetic Models Target-Controlled Infusions. Of the many available models, the two most widely used propofol kinetic models for TCI are those published by Marsh and associates and Schnider and associates.[31,32] In addition to model selection, as with bolus and continuous infusion dosing, identifying the ideal weight scalar to use is also important.

The Marsh model, although useful, was built from data collected in a pediatric population. Researchers have explored different dosing weights using this model in morbidly obese patients when coadministered with remifentanil with varied results. Albertin and colleagues[29] used CBW to dose a propofol TCI using the Marsh model. They found predicted substantially overestimated measured propofol concentrations and expressed concern for intraoperative awareness when using CBW with the Marsh TCI model. The same group[33] compared the predictive performance of the TCI using CBW versus TBW and found that CBW performed worse than TBW. They concluded that TBW, not CBW, should be used to administer propofol via TCI to morbidly obese patients. In contrast, recently, Cortinez and colleagues[34] evaluated the several pharmacokinetic models, and the use of CBW with the Marsh and Schnider models (described later) showed acceptable prediction performances. They stated that with both models using CBW is one of the best options for propofol TCI in obese patients, as their opinion. In any case, electroencephalographic monitoring is recommended to avoid the risk of awareness.

The Schnider model, although built from data collected in adults over a range of weights, heights, and ages, does not specifically include obese patients. This model uses the weight scalar LBM, which has limited application in morbidly obese patients.[32]

For comparison, the Marsh or the Schnider model has been applied on morbidly obese patients. Echevarria and colleagues[35] reported differences in effect-site propofol concentrations with a BIS of less than 60 between the two pharmacokinetic models when used for induction in morbidly obese patients. To achieve a 95% probability of effect, target concentrations of 4.2 and 5.5 μg/mL were required for the Marsh and Schnider models, respectively. This difference occurred because of the potential prediction errors in each pharmacokinetic model that was used (the actual drug concentrations in each patient are unknown).

Cortinez and colleagues used an international data repository called Open TCI (http://www.opentci.org) to build a model using propofol concentrations from a wide range of body weights.[36] They built a propofol kinetic model that scales normal-size to obese individuals using an empirically derived formula that uses allometric scaling. In this formula, TBW accounts for differences in distribution and clearances in obese patients. TBW is divided by a standard patient size (70 kg) and raised to the power of 1 for distribution volumes and by the power of 0.75 for clearances. Van Kralingen and colleagues[37] further modified this approach and reported better model performance with exponents of 0.71 for clearance. Eleveld and colleagues[38] constructed a general purpose allometric pharmacokinetic model for propofol using a large dataset containing data from young children, children, adults, elderly, and obese individuals (pharmacokinetic parameter estimates can be calculated by entering patient demographics at http://www.eurosiva.eu/tivatrainer/modeltranslate/calc_compartments.html; last accessed 2018/01/05). Cortinez and colleagues[34] evaluated the predictive performances of the five foregoing models (i.e., Marsh, Schnider, Cortinez, Van Kralingen, and Eleveld models) in data from obese patients and found that

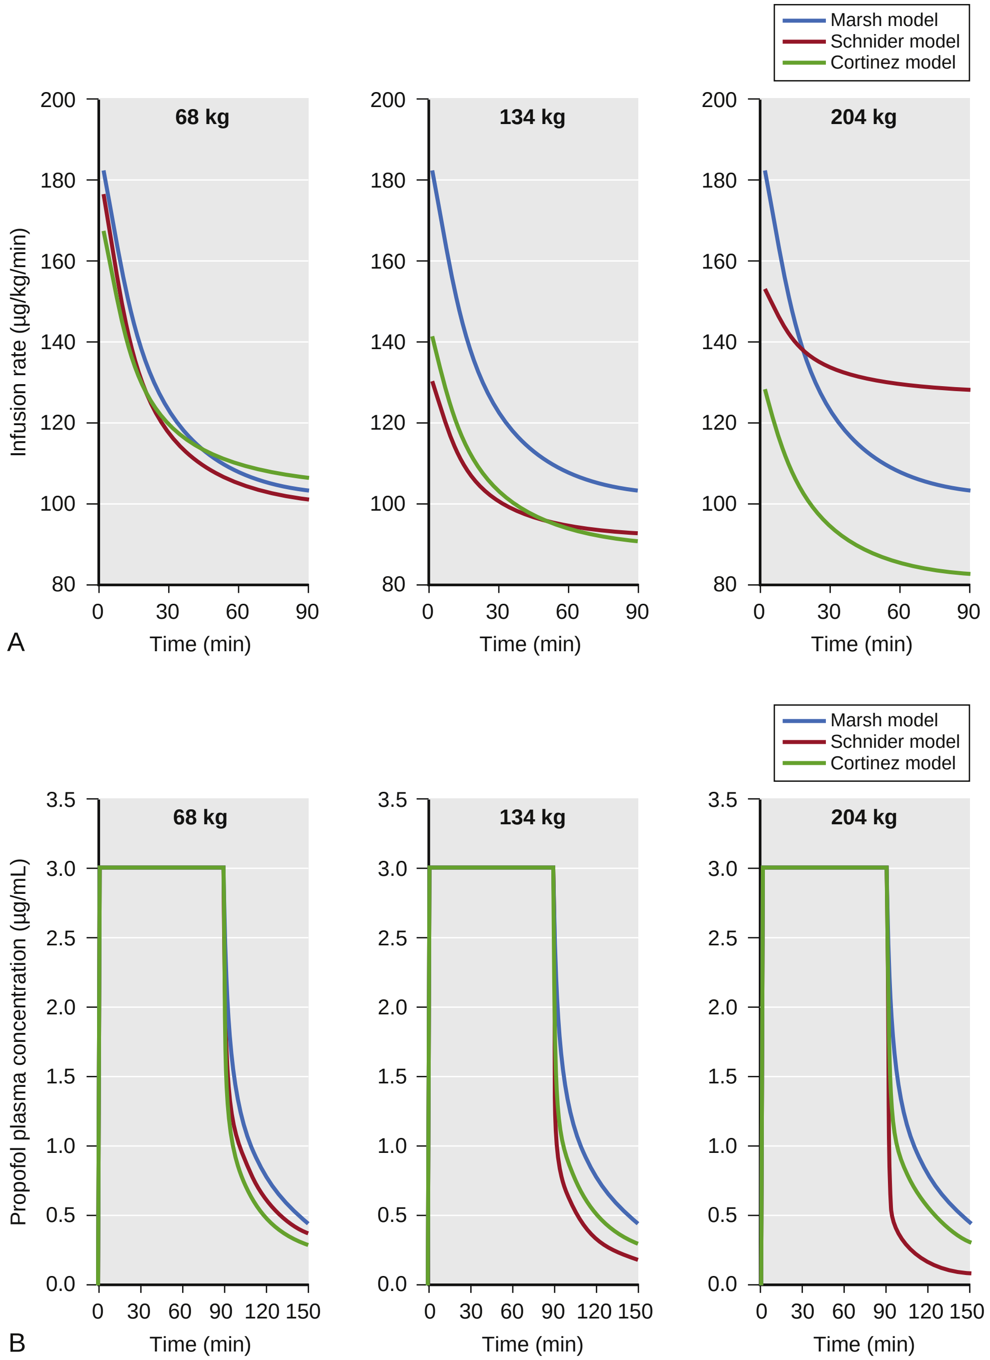

Fig.18.34 Simulations of a 90-minute propofol target-controlled infusion set to achieve and maintain a plasma concentration (Cp) of 3 µg/mL using four different published propofol pharmacokinetic models: Marsh and associates,[31] Schnider and associates,[32] Cortinez and associates,[36] and Eleveld and associates.[36,38] Simulations assumed 40-year-old males who are 176 cm tall and weigh 68, 134, or 204 kg. (A) Propofol infusion rates for each model at each weight. (B) Propofol plasma concentrations predicted by each model for each weight.

the Eleveld allometric pharmacokinetic model performed best. They stated that the Eleveld model using TBW is one of the best options for propofol TCI in obese patients.

Fig. 18.34 presents a simulation of propofol infusion rates and associated plasma concentrations using the Marsh, Schnider, Cortinez, and Eleveld models to drive a TCI to achieve a concentration of 3 µg/mL. Key points from this simulation include: TCI infusions based on the Marsh model are linear to TBW such that the infusion rates and plasma concentrations are identical across weights. With an increase in body weights, the degree of increase in total propofol amounts for TCI administrations is smaller with the Cortinez and Eleveld models than with the Marsh and Schnider models.

For propofol, the Eleveld model may be best suited for TCI in obese and morbidly obese patients. Unfortunately, this model is not yet available in many commercial TCI pumps. One caveat that is important to consider is that model differences are likely overshadowed by inter-individual variability. In sum, any one of the four models will likely yield similar clinical results if titrated to effect in conjunction with processed EEG monitoring.

Other Sedatives. Only limited information is available on the behavior of other sedatives (i.e., midazolam, ketamine, etomidate, dexmedetomidine, and barbiturates) in obese patients. In a study by Greenblatt and associates, the volume of distribution even when normalized to weight (e.g., L/kg) was larger in obese patients, suggesting that lean tissue may take up less midazolam than adipose tissue.[39] Thus, midazolam's distribution volume follows the TBW: as patient size increases, so does the distribution volume. In addition, midazolam elimination was the same in all study subjects (lean or obese). This suggests that regardless of dose, hepatic metabolism of midazolam is fixed and elimination will require more time in obese patients. Another interesting finding was that time to peak concentration and peak plasma drug concentrations were the same when administered in a weight-normalized fashion regardless of body habitus.

Although not clinically validated in obese patients, the authors recommend that bolus doses should be scaled to TBW and other dosing scalars may lead to inadequate effect. On the other hand, with a fixed elimination, continuous infusion rates should be dosed to IBW.[39]

Cortinez and colleagues[40] characterized the influence of obesity on pharmacokinetics of dexmedetomidine and found that fat mass is not related to a proportional increase in distribution volume and is associated with the impairment of clearance. Xu and colleagues[41] performed noncompartment pharmacokinetic analysis of dexmedetomidine with dosing calculated on TBW. In obese patients, higher initial concentrations and lower clearance per kg, and deeper sedation with lower SpO_2 values were observed. These results suggest that dosing of dexmedetomidine, which is calculated using TBW, can be overdosing in these populations.

OPIOIDS

With the exception of remifentanil, minimal work has explored the implication of obesity on the kinetic and dynamic behavior of opioids.

Remifentanil

In obese patients, largely due to its rapid metabolism by nonspecific esterases, the distribution volume and clearance of remifentanil are similar in lean and obese patients.[42] As with propofol, researchers have explored several scaled weights in an effort to optimize bolus dosing, continuous infusions, and TCIs.

Dosing Scalars

As previously noted with propofol, simulation is used to present the predicted remifentanil effect-site concentrations and analgesic effect for a variety of scaled weights in individuals 174 cm in height, some obese (185 kg, BMI of 60) and lean (68 kg, BMI of 22) (Fig. 18.35). Several key points are illustrated in these simulations:

1. For an obese patient, dosing scaled to FFM resulted in almost identical remifentanil effect-site concentrations as in the lean patient dosed according to TBW. Unlike propofol, dosing remifentanil to CBW *(red line)* leads to higher plasma concentrations compared with levels achieved when dosing to TBW in a lean individual.
2. Dosing scaled to LBM in the obese individual resulted in lower effect-site concentrations than those in a lean individual dosed according to TBW.

Remifentanil Kinetic Models for Target-Controlled Infusions

For remifentanil TCI, there is one available pharmacokinetic model published by Minto and associates.[43] Although built from data collected in adults over a range of weights, heights, and ages, obese patients and morbidly obese patients were not included. Many of the model parameters are scaled to LBM. As previously discussed, this may limit the application of this model in the morbidly obese. Kim and colleagues[44] developed a new population pharmacokinetic model for remifentanil that characterize the influence of

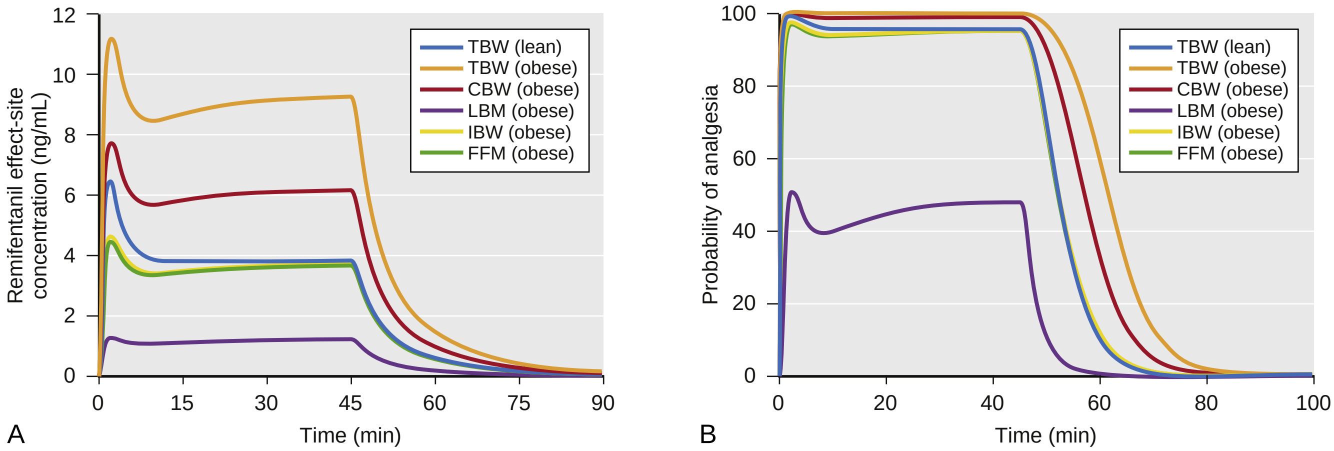

Fig. 18.35 (A and B) Simulations of remifentanil effect-site concentrations (A) and analgesic effect (B) that result from a 1 μg/kg bolus and a 60-minute infusion at a rate of 0.15 μg/kg/min to a 40-year-old male who is 176 cm tall. Simulations include the following dosing weights: total body weights *(TBW)* of 68 kg and 185 kg (body mass indices of 22 and 60, respectively) and scaled weights for the 185-kg weight to include Servin's corrected body weight *(CBW)*, lean body mass *(LBM)*, ideal body weight *(IBW)*, and fat free mass *(FFM)*. Remifentanil effect-site concentrations and estimates of analgesic effect were estimated using published pharmacokinetic models. (From Minto CF, Schnider TW, Egan TD, et al. Influence of age and gender on the pharmacokinetics and pharmacodynamics of remifentanil. I. Model development. *Anesthesiology*. 1997;86(1):10–23.)

body weight using allometric body mass scaling in the general adult population.

Fig. 18.36 presents a simulation of the predicted remifentanil plasma concentrations based on the Minto and Kim models. The Minto model overestimates remifentanil concentrations with increasing weight. This is likely due to the use of LBM when estimating pharmacokinetic parameters.

In summary, available models (Minto or Kim) are appropriate for TCI in this patient group but will administer different amounts of remifentanil and require titration to achieve desired yet avoid adverse clinical effects.

FENTANYL

Despite widespread use in the clinical arena, relatively little work has explored how obesity impacts fentanyl pharmacokinetics. Published fentanyl pharmacokinetic models[45] tend to overestimate fentanyl concentrations as TBW increases. A fentanyl kinetic model based on data collected in obese subjects has not (yet) been published. Shibutani and colleagues[46,47] explored ways to improve predictions using published models by modifying demographic data (e.g., either height or weight). They characterized a nonlinear relationship between fentanyl clearance and TBW and recommended the use of a modified weight, called the pharmacokinetic mass, to improve the predictive performance of one of the many available fentanyl kinetic models, a model published by Shafer and colleagues. They explored the use of pharmacokinetic mass when dosing obese patients with fentanyl in a postoperative setting. They found that dosing based on TBW may be excessive.[36]

Other Opioids

Even less information regarding the impact of obesity on drug behavior is available for opioids other than remifentanil and fentanyl. Sufentanil has been studied in obese patients, where its volume of distribution increases linearly with TBW[48] and clearance was similar between lean and obese individuals. It was recommended that bolus dosing use TBW and “prudently reduced” dosing for continuous infusions. For TCI, Slepchenko and colleagues found model estimates of sufentanil concentrations accurately predicted measured concentrations in morbidly obese patients[49] using a previously published mode of sufentanil kinetics by Gepts and associates.[50] This is likely due to the fact that the kinetic model was built from measured concentrations in patients with a weight range of 47 to 94 kg. de Hoogd and colleagues[51] performed a population pharmacokinetic analysis of intravenous morphine in morbidly obese individuals. They found that morphine pharmacokinetics were comparable to those of healthy volunteers. They concluded that no weight-based dosing adjustments were necessary. However, they also found that the elimination of pharmacologically active metabolite was decreased, resulting in an increased exposure to active metabolite with prolonged administrations. They concluded that the clinical relevance of this phenomenon was not clear.

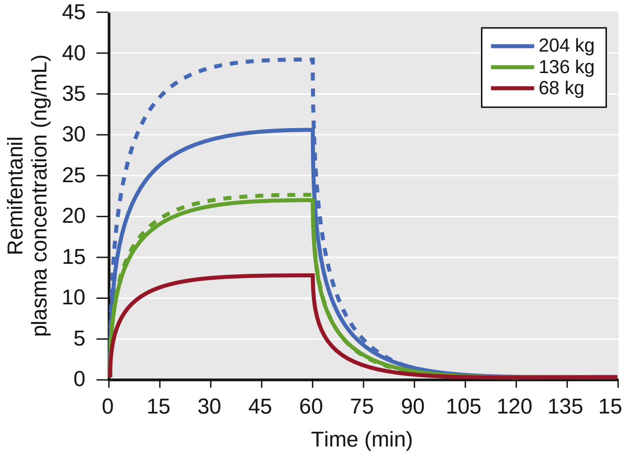

Fig. 18.36 Simulations of remifentanil plasma concentrations that result from a 60-minute infusion (0.5 μg/kg/min) in a 40-year-old male, 176 cm tall. The simulations include three total body weights: 68, 136, and 204 kg with body mass indices of 22, 44, and 66, respectively. Simulations were performed using pharmacokinetic parameters published by Minto and associates[43] *(dashed lines)* and Kim and colleagues[44] *(solid lines)*. In an extremely obese (204 kg) individual, Minto's model predicts very high remifentanil concentrations.

INHALED ANESTHETICS

The perception of volatile anesthetics is that they accumulate more in obese than in lean patients and that this leads to prolonged emergence. Studies on inhalation anesthetics in obese individuals, however, have not confirmed this perception.[52] Two phenomena contribute to this observation: first, blood flow to adipose tissue *decreases* with increasing obesity,[53] and second, the time required to fill adipose tissue with volatile anesthetics is long. The time required to achieve 63% of the final equilibrium within adipose tissue for desflurane and isoflurane are longer than 22 and 35 hours, respectively.[54,55]

INFLUENCE OF AGE ON ANESTHETIC DRUG PHARMACOLOGY

Clinicians are often faced with anesthetizing elderly adults and have long recognized that they usually require a smaller dosage of most anesthetics to produce the desired therapeutic effect while minimizing adverse effects. Age is one of the most valuable in covariates to consider when developing an anesthetic plan. The influence of age on pharmacokinetics and pharmacodynamics of many anesthetics has been well described. As with obesity, both remifentanil and propofol can serve as prototypes to understand how age influences anesthetic drug behavior. Studies specifically designed to assess the influence of age on remifentanil and propofol have characterized the influence of age in quantitative terms.[32,38,43,44,56,57]

With remifentanil, elderly patients require less drug to produce an opioid effect. Reduced doses are primarily a function of changes in pharmacodynamics, but may involve pharmacokinetic changes as well.[43] The concentration required to produce electroencephalographic changes is decreased. Based on previously published pharmacokinetic and pharmacodynamic models built from measurements over a wide age range,[32,43,56,57] simulations can be performed to explore how age may influence dosing. For example, to achieve equipotent doses in 20- and 80-year-olds, the dose for the 80-year-old should be reduced by 55%. A similar analysis for propofol recommends that the dose for an 80-year-old should be reduced by 65% compared to that of a 20-year-old.

The mechanisms for these changes are not clear, especially for pharmacodynamic changes. One possible source of change in pharmacokinetic behavior may be due to decreased cardiac output. Lower cardiac output in the elderly[58] results in slower circulation and subsequent changes in drug distribution and redistribution. This may lead to high peak concentrations[58,59] and decreased drug delivery to metabolic organs and reduced clearance. This is consistent with what has been reported for many intravenous anesthetics (propofol, thiopental, and etomidate), which have slower clearance and a smaller volume of distribution.[32,60–62] Beyond age-related changes in cardiac output, it is important to consider comorbidities that may reduce cardiovascular function.[63] Taking this into account, anesthesiologists often consider a patient's "physiologic" age instead of solely relying on actual age.[64,65] For some older adult patients, such as those with no significant coexisting disease, normal body habitus, and good exercise tolerance, a substantial reduction in dose may not be warranted.

Summary

This chapter reviewed basic principles of clinical pharmacology used to describe anesthetic drug behavior: pharmacokinetics, pharmacodynamics, and anesthetic drug interactions. These principles provide the information needed to make rational decisions about the selection and administration of anesthetics. From a practical aspect, these principles characterize the magnitude and time course of drug effect, but because of complex math requirements, they have limited clinical utility in everyday practice. Advances in computer simulation, however, have brought this capability to the point of real-time patient care. Perhaps one of the most important advances in our understanding of clinical pharmacology is the development of interaction models that describe how different classes of anesthetic drugs influence one another. This is especially relevant to anesthesiologists, given that they rarely use just one drug when providing anesthesia.

Inhaled Anesthetics: Mechanisms of Action

MISHA PEROUANSKY, ROBERT A. PEARCE, HUGH C. HEMMINGS, and
NICHOLAS P. FRANKS

KEY POINTS

- Anesthesia consists of separable and independent components, each of which involves distinct, but possibly overlapping, mechanisms at different sites in the central nervous system.
- The potencies of general anesthetics correlate with their solubility in oil, indicating the importance of interactions with predominantly hydrophobic targets.
- General anesthetics act by binding directly to amphiphilic cavities in proteins. Binding sites have been identified by a combination of site-directed mutagenesis and high-resolution structural analysis of anesthetic binding.
- Mutations made to render putative protein targets insensitive to inhaled anesthetics have been expressed in mice but have not generated breakthroughs analogous to the success of this strategy with intravenous anesthetics.
- The effects of inhaled anesthetics cannot be explained by a single molecular mechanism. Rather, several targets contribute to the component actions comprising the anesthetic effects of each anesthetic. However, these effects do converge on a limited number of states underlying the behavioral effects.
- The immobilizing effect of inhaled anesthetics involves actions in the spinal cord, whereas sedation/hypnosis and amnesia involve supraspinal mechanisms that interact with endogenous memory, sleep, and consciousness pathways and networks.
- Volatile inhaled anesthetics enhance inhibitory synaptic transmission postsynaptically by potentiating ligand-gated ion channels activated by γ-aminobutyric acid (GABA) and glycine, extrasynaptically by enhancing GABA receptors, and presynaptically by enhancing basal GABA release.
- Inhaled anesthetics suppress excitatory synaptic transmission presynaptically by reducing glutamate release (volatile anesthetics) and postsynaptically by inhibiting excitatory ionotropic receptors activated by glutamate (gaseous and to some extent volatile anesthetics).
- Inhaled anesthetics directly activate certain two-pore-domain potassium channels, which is likely to result in both pre- and post-synaptic effects.
- There is as yet no comprehensive theory of anesthesia that describes the sequence of events leading from the interaction between an anesthetic molecule and its targets to the behavioral effects.

Despite the widespread clinical use of general anesthetics, our current understanding of their molecular, cellular, and network mechanisms is incomplete. This critical gap in the pharmacology of one of medicine's most important drug classes not only impedes rational use of available anesthetics but also hinders the development of newer anesthetics that might selectively achieve the desirable end points of anesthesia with fewer adverse cardiovascular, respiratory, and possibly neuropathologic side effects. Although major progress has been made in understanding the pharmacology of the intravenous anesthetics by molecular genetic approaches, the actions of the inhaled anesthetics at the molecular and cellular levels are more enigmatic. It is still not possible to trace precisely the sequence of events that leads from inhaled anesthetic-target interactions, through ascending levels of biologic complexity, to the various behavioral effects that characterize the composite state of clinical anesthesia in humans. Nevertheless, investigations continue to reveal fundamental principles of action and have led to a framework for understanding anesthetic effects at different organizational levels.

The focus of this chapter is on the mechanisms involved in the principal therapeutic effects (anesthesia) and on the side effects of the inhaled anesthetics (Fig. 19.1), a chemically and pharmacologically diverse group that includes

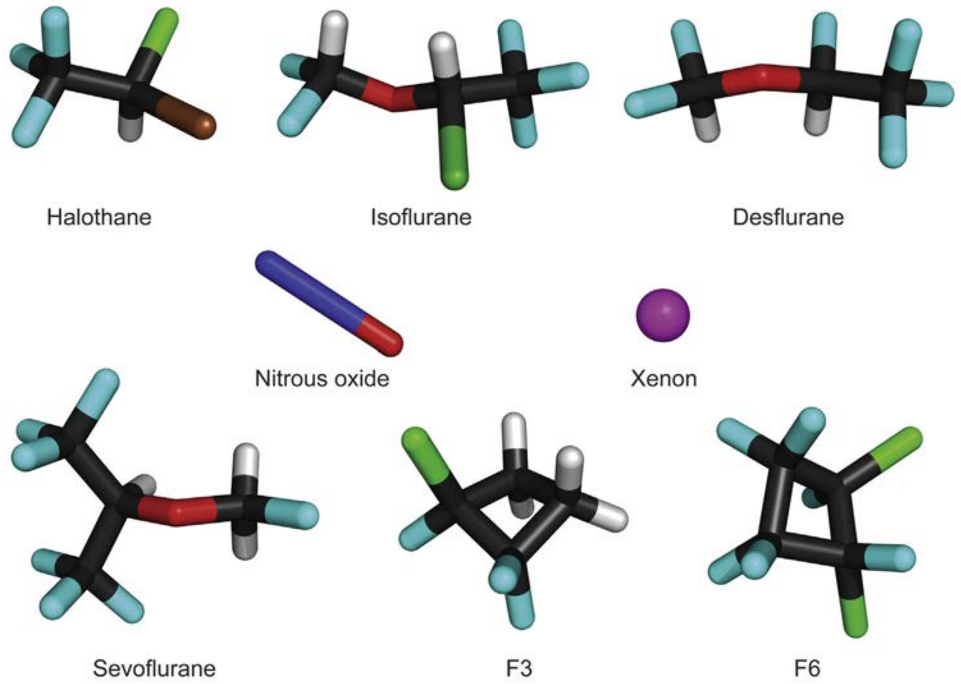

Fig. 19.1 Structures of some representative general anesthetics and a nonimmobilizer *(F6)*. The colors are bromine *(brown)*, carbon *(black)*, chlorine *(green)*, fluorine *(cyan)*, hydrogen *(gray)*, nitrogen *(blue)*, oxygen *(red)*, and xenon *(magenta)*. Note that halothane, isoflurane, desflurane, and *F3* all contain a chiral carbon; therefore each exists as two mirror-image enantiomers (only one enantiomer is shown). Also, the nonimmobilizer *F6* contains two chiral carbons and exists as two trans enantiomers and one cis stereoisomer (only one of the enantiomers is shown).

the potent halogenated ether (isoflurane, sevoflurane, desflurane, enflurane) and alkane (halothane) volatile anesthetics and the inorganic gaseous anesthetics (nitrous oxide and xenon). This critical summary of the current state of knowledge begins with an historical overview and a review of the behavioral end points of anesthesia. We then trace, where possible, inhaled anesthetic effects through ascending levels of organization from molecules, cells, circuits, networks, and organs to mammalian behavior. We also briefly address studies of anesthetic effects in very simple model organisms, with anesthetic end points being identified that as yet bear uncertain relationships to those in mammals.[1]

History

THE UNIFIED PARADIGM OF ANESTHETIC THEORIES

The first monograph reporting experimental work on anesthetic mechanisms, proposing a soon-to-be discredited lipid-elution theory of anesthetic action, was published only 6 months after Morton's public demonstration of ether anesthesia in Boston's Ether Dome. For decades thereafter, the phenomenon of anesthesia puzzled, inspired, and awed those who tried to understand it. An influential paradigm of anesthetic action formulated by Claude Bernard in the 1870s posited that anesthesia was a "unified" phenomenon—a unitary mechanism applicable to all forms of life. Although the anesthetized state could be brought about by a variety of agents, its essence was the same in all living creatures. In fact, Bernard thought that life itself was defined by susceptibility to anesthesia. Bernard also proposed a more specific theory of anesthesia, coagulation of protoplasm, which competed with a number of coexisting theories entertained by the scientific community. In a major work published in 1919, Hans Winterstein[2] summarized the perplexing diversity of anesthetic theories by listing more than 600 references, the majority to original laboratory work—a convincing testimony to the interest of the scientific world in this phenomenon. Of note, the work of Meyer and Overton at the end of the nineteenth century had only a limited effect on the trajectory of research until the 1960s. Only then was the striking simplicity of the Meyer-Overton correlation (Fig. 19.2*A*) of anesthetic potency with solubility in olive oil interpreted by the majority of researchers to indicate that lipids are likely to be the anesthetic target. This interpretation focused attention on anesthetic effects on the bulk physical properties of cell membranes, which were known to consist primarily of lipid molecules. Such nonspecific or "lipoid-based" anesthetic theories dominated the field from the 1960s to the 1980s.

MINIMUM ALVEOLAR CONCENTRATION—A BRIDGE BETWEEN PAST AND PRESENT

The potencies of inhaled anesthetics for immobilization were established in the classic studies in the 1960s of Eger and colleagues,[3,4] who defined the *minimum alveolar concentration* (MAC) as the inhaled anesthetic atmospheric pressure required to prevent movement in response to a defined noxious stimulus in 50% of subjects. The concept of MAC evolved within a unitary paradigm of anesthetic action and also reflected the priorities of clinical practice. As a result, prevention of movement (immobility) became a

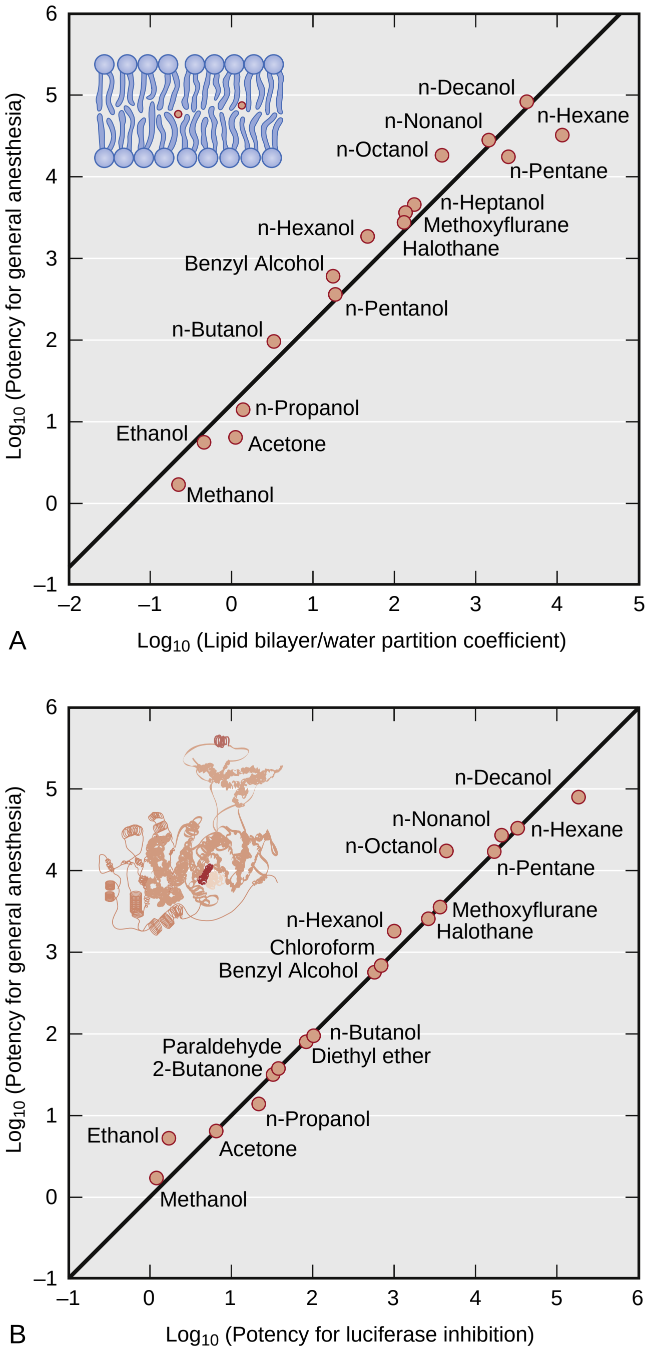

Fig. 19.2 General anesthetics act by binding directly to proteins. (A) The iconic Meyer-Overton correlation (c.1900) between anesthetic potency and the lipid-water partition coefficient was initially interpreted as evidence that lipids of nerve membranes were the principal anesthetic target sites. (B) Progress in the 20th century showed that general anesthetic potencies correlate equally well with their ability to inhibit activity of the soluble firefly enzyme luciferase, which is not a physiologically relevant anesthetic target itself but serves as a lipid-free model protein for anesthetic binding. *Inset*, The crystal structure of luciferase[110] with bound anesthetic *(red)*. (Reprinted with permission from Franks NP, Lieb WR. Molecular and cellular mechanisms of general anesthesia. *Nature*. 1994;367:607–614.)

universal yardstick for anesthetic effects, presumed to occur in the brain. Moreover, the simple elegance of the relationship between anesthetic potency and lipid solubility (see Fig. 19.2*A*) graphically illustrated Meyer and Overton's conclusion that "All chemically indifferent substances that are soluble in fat are anesthetics. Their relative potency as anesthetics will depend on their affinity to fat on the one hand and water on the other hand, that is, on the fat/water partition coefficient."[1] This was interpreted as favoring lipids as the primary targets of anesthetics and a single nonspecific theory to explain anesthesia. The appeal of a single unified mechanism to explain anesthesia was (and remains) intellectually appealing. This focused the bulk of research efforts on delineating how anesthetic interactions with lipid membranes might lead to the behavioral changes observed under anesthesia—the nonspecific lipoid theory.

Because inhaled anesthetic concentrations reflect concentrations in the tissues after equilibration, which is most rapidly achieved for well-perfused organs such as the brain and heart, MAC is analogous to the plasma concentration for 50% effect (EC_{50}) for intravenous anesthetics. In clinical applications, MAC is usually expressed as volume percent (vol%), which varies considerably with temperature owing to the large temperature dependence of partitioning between the gas phase and condensed phases (be they water, lipids, or proteins), whereas the equivalent condensed-phase molar concentrations are much less dependent on temperature.[5] The MAC concept provided researchers and clinicians with a universal standard whereby to measure a defined anesthetic end point (immobility), making meaningful comparisons of experimental results possible and accelerating clinical and laboratory research into anesthetic mechanisms. Today, a more nuanced understanding of MAC considers the structural and functional diversity of the physiologic targets for the different components of the anesthetic state.

SHIFT FROM LIPID- TO PROTEIN-CENTERED MECHANISMS

Lipid-centered mechanisms of anesthesia prevailed in the two decades after definition of the MAC concept. Alternative targets were occasionally proposed but largely neglected by the scientific mainstream. Experimental inconsistencies of lipid targets,[6-8] as well as evidence compatible with proteins as primary sites of action,[9,10] were largely ignored. A shift from lipid- to protein-centered mechanisms, however, began in the late 1970s, owing largely to the discoveries of Franks and Lieb,[11-15] who in an influential series of publications demonstrated that not only were lipids implausible targets but that protein targets were also compatible with the Meyer-Overton correlation (see Fig. 19.2*B*)—a proof of concept that, within a few years, redirected the bulk of research efforts toward proteins. As a corollary of this reorientation, evidence against lipid-based theories was recognized. Examples include the cutoff in anesthetic potency in homologous series of long-chain anesthetic alcohols[15,16] and the identification of hydrophobic drugs that do not obey the Meyer-Overton correlation.[1,17] The enantiomeric selectivity of several anesthetics further strengthened the case for specific binding sites on proteins because stereoselectivity is difficult to reconcile with lipid targets.[18-20] Today, there is widespread acceptance of the notion that lipid bilayers remain essentially unaffected by general anesthetics[11,21] and that critical signaling proteins (e.g., ion channels or ligand-gated receptors) are the relevant molecular targets of anesthetic action.[22] The exact identity of proteins contributing to specific anesthetic end points continues to be sought, with research addressing not only the "where" (target) but also the "how" (process) of anesthetic mechanisms.

DIVERSITY OF POTENTIAL ANESTHETIC TARGETS

At high concentrations in vitro, most inhaled anesthetics affect the functions of multiple proteins, several of which might be plausibly connected to the components of the anesthetic state or anesthetic side effects. However, when a specific anesthetic end point is considered, anesthetics are effective in vivo over a very narrow concentration range. This makes the concentration at which a relevant anesthetic effect is observed a critical consideration for deciding potential relevance. The mechanistic relevance of small effects observed in vitro at relevant concentrations is less clear; that is, what effect is too small to be considered relevant to anesthesia?[23-25]

Whether anesthesia results from the sum of minor perturbations at multiple sites or from substantial effects on a small number of targets remains to be determined. This should be resolved as more sophisticated molecular genetics experimental techniques are applied to test the relevance of putative targets. There are two reasons for believing that the number of relevant targets may be small. First, the extreme steepness of anesthetic concentration-response curves means that, for a given end point, substantial effects on two or three targets would be sufficient to account entirely for the in vivo effect. Second, the stereoselectivity observed in vivo[26] is comparable to the largest effects seen in putative targets in vitro,[18,20] suggesting that only a small number of targets are likely to be involved. Set against this logic is the experimental evidence that a rather large number of plausible target proteins are affected, albeit usually to small extents, and determining which of these are relevant to the various anesthetic end points remains a challenge.

ANESTHESIA: A COMPOSITE NEUROPHARMACOLOGIC STATE

Along with progress in identifying the molecular mechanisms of anesthesia, our understanding of the nature of the anesthetic state has evolved. Whereas a drug-induced coma-like state of general anesthesia can be induced by inhaled anesthetics administered at appropriate concentrations (approximately 1.3 times MAC, equivalent to the EC_{95} of an intravenous anesthetic), the use of such high concentrations can lead to short- and possibly long-term side effects. It is now clear that anesthesia consists of separable and at least partially independent components or substates, each of which involves distinct but possibly overlapping mechanisms in different regions of the central nervous system (CNS) and with variations in relative potencies between specific agents.[27] Immobilization, the core measure of MAC, is mediated largely at the level of the spinal cord by inhaled anesthetics[28,29] but not by barbiturates.[30] On the other hand, the spinal cord is clearly not the primary site of such phenomena as amnesia, sedation, and unconsciousness, which rather are produced by anesthetic effects on cerebral cortical function (Fig. 19.3). A functional separation between amnesia and sedation has been demonstrated for intravenous anesthetics,[31] and it seems likely that this will apply to inhaled anesthetics as well. The state commonly referred to as "unconsciousness" is in itself heterogeneous, with evidence for distinct states of unresponsiveness and unconsciousness.[32] These and similar findings have led to the concept that general anesthesia consists of multiple independent components that can be resolved experimentally and clinically.

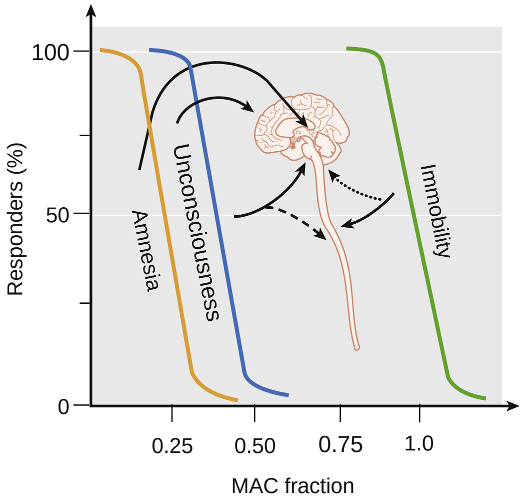

Fig. 19.3 Several behavioral end points and sites of action underlie inhaled anesthetic action. Amnesia, the most sensitive anesthetic end point, probably involves the hippocampus, amygdala, mediotemporal lobe, and other cortical structures. Unconsciousness likely involves the cerebral cortex, thalamus, and neuronal pathways of sleep and arousal. Sedation and hypnosis (loss of responsiveness) are part of the consciousness-unconsciousness continuum and are not shown. Immobility occurs by anesthetic action in the spinal cord, although supraspinal effects *(dotted arrow)* are likely to be important for some anesthetics. Anesthetic action in the spinal cord blunts ascending impulses arising from noxious stimulation and might indirectly contribute to anesthetic-induced unconsciousness and amnesia *(dashed arrow)*. Cardiovascular responses occur at even greater MAC fractions (not shown). (Courtesy Joseph Antognini, University of California, Davis, CA.)

In principle, each component of anesthesia can be preferentially induced in a concentration- and agent-specific manner using individual cellular/molecular pathways in various regions of the CNS. For example, injections of pentobarbital into discrete sites in the mesopontine tegmentum induce a comatose state,[33,34] whereas sedation induced by systemic administration of propofol can be reversed by microinjections of γ-aminobutyric acid $(GABA)_A$ receptor antagonists into the tuberomammillary nucleus, a sleep-regulating nucleus in the hypothalamus.[35] Thus general anesthetics produce separate identifiable anesthetic substates via agent-specific actions at discrete anatomic sites in the CNS through different molecular targets. An important consequence of this complexity is that MAC, which is based exclusively on a motor response, might not proportionately reflect other components of anesthesia. Although this heterogeneity of anesthetic actions complicates a mechanistic understanding, it does open the possibility of developing substate-specific drugs.

Integrated Effects on Central Nervous System Function

IMMOBILITY

Electroencephalography as a monitor of brain activity has been applied both to the study of anesthetic mechanisms and as a monitor of the anesthetic state. Failure to find a correlation between quantitative electroencephalographic activity and immobility in response to noxious stimulation led to the somewhat radical (at the time) hypothesis that immobility was not a cerebral cortex–mediated phenomenon.[36] Experimental demonstration that volatile anesthetics act on the spinal cord to suppress movement[28,29] supported this hypothesis and was a major factor leading to the contemporary separation of anesthetic substates, of which immobility requires the highest drug concentrations (see Fig. 19.3). Taking advantage of the atypical blood supply of goat CNS, which allows separate experimental perfusion of the brain and spinal cord, Antognini and colleagues[28,37] showed that immobility involves anesthetic effects at the spinal level because selective delivery of isoflurane or halothane only to the brain required 2.5-fold to 4-fold higher concentrations compared with delivery to the whole CNS. At the same time, experiments by Rampil and colleagues[29] that used surgical separation of the forebrain and midbrain from the spinal cord in rats led to the conclusion that immobilization involves primarily suppression of the nocifensive withdrawal reflex arc at the level of the spinal cord (Fig. 19.4).

In the 25 years since the identification of the spinal cord as the site of anesthetic-induced immobility, research has centered on pharmacologic, genetic, and complex network approaches. The conventional pharmacologic approach ("bulk" administration of agonists and antagonists into the CNS) to identify receptor-level contributions to isoflurane-induced immobility (isoflurane being the standard potent ether for experimental purposes) has severe limitations in the complex networks of the CNS. Nevertheless, it yielded at least one surprising insight—that actions at $GABA_A$ receptors appear not to be important for the end point of immobility, at least where inhalational agents are concerned.[38] Anesthetic-resistant transgenic mice confirmed that $GABA_A$ receptors containing α1- or α3-subunits do not contribute to the immobilizing action of isoflurane.[39,40] Perhaps less surprisingly, inhibition of central nicotinic acetylcholine receptors also plays no role in immobilization.[41] A role for voltage-gated sodium (Na^+) channels was suggested by the finding that intrathecal administration of a selective inhibitor of Na^+ channels potentiates anesthetic immobility (reduces MAC), whereas an enhancer of Na^+ channel activity does the opposite.[42]

In contrast, work in mutant mice suggests a potential role for tandem-pore domain potassium channels (K_{2P}) in anesthetic-induced immobility. Global knockout mice lacking the TASK-1, TASK-3, and TREK-1 K_{2P} channels are less sensitive to volatile but not intravenous anesthetics,[43-46] indicating a role for these channels possibly by a presynaptic mechanism.[47] An important limitation is that global knockout results almost invariably in wide-ranging compensatory changes in the molecular landscape of the organism with unpredictable consequences for the phenomenon under investigation.

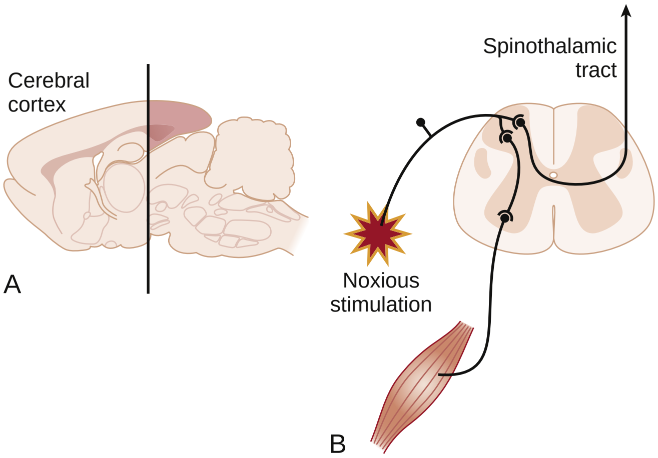

Fig. 19.4 Inhaled anesthetics produce immobility at the spinal level. (A) Decerebration by removal of the forebrain rostral to the *black line* does not alter the minimum alveolar concentration of isoflurane in rats, indicating that volatile anesthetic immobilization does not depend on the cerebral cortex.[28,29] (B) Anesthetics suppress the nocifensive withdrawal reflex response to noxious stimulation transmitted to the dorsal horn by sensory nerves at the spinal level. Current efforts are focused on identifying the molecular, cellular, and anatomic substrates for this effect.

Work with ex vivo preparations that attempt to preserve parts of the complex spinal cord circuitry suggests that anesthetic inhibition of afferent (noxious sensory) input to the dorsal horn plays a subordinate role to the suppression of the efferent (motor) output from the ventral horn, although this may vary by specific agent. This motor output is coordinated by neuronal networks organized in so-called central pattern generators that control the activity of cholinergic motoneurons.[48] Not unlike understanding the anesthetic effects on higher cognitive function, the key to understanding immobility will likely lie in resolving the effect of anesthetics on integrated spinal network activity after understanding the circuit physiology.

UNCONSCIOUSNESS

Compared with the other end points of anesthesia, research into the biologic basis of anesthetic-induced unconsciousness is relatively recent, but it has become an area of active investigation. Research is being conducted in animal models and human subjects and commercial interests are working to develop effective depth-of-anesthesia monitors. These efforts reflect increasing interest, and progress, in "consciousness science" in general.[49,50] Moreover, anesthetics are themselves being used as research tools to help unravel the neuronal underpinnings of consciousness.

Loss of consciousness (or hypnosis) is a hallmark of the onset of anesthesia. However, what is commonly referred to as *unconsciousness under anesthesia* might be more accurately described as *unresponsiveness,* a condition that could also encompass states of self-awareness without environmental awareness (as in dreaming) or environmental awareness without recall (e.g. conscious amnesia combined with neuromuscular paralysis during induction of anesthesia).[32,51]

Numerous theories have been advanced to explain anesthetic-induced unconsciousness. They can generally be divided into those that address "bottom-up" changes in the brain stem circuitry that controls arousal,[52,53] versus "top-down" changes in the thalamocortical circuits that integrate information.[54] Indeed, this distinction formed the basis for a recent suggestion that the *level* of consciousness reflects bottom-up processes whereas the *content* of consciousness reflects top-down processes—a notion with intuitive appeal.[55]

One of the most influential theories has been the "integrated information theory of consciousness (IITC)" of Tononi,[56] which emphasizes the need for simultaneous differentiation between brain states and their integration into a coherent whole.[57] Drugs or diseases that suppress consciousness could act through either process. Other information-based approaches use symbolic analysis,[58] transfer entropy,[59] chaos theory,[60] and more. The rich connectivity of the cerebral cortex and its hierarchical organization are especially suited to enable high levels of information integration in the human brain. Some brain areas present a "rich club" organization (i.e., highly connected nodes tend to be preferentially connected to other highly connected nodes), which has been suggested to be optimal for information integration.[61,62] These hubs are promising targets for the hypnotic action of general anesthetic drugs.

Anesthetics might act by interfering with the operational synchronicity and coherence of corticothalamic networks. Consequent disruption of functional and effective connectivity has been observed during natural slow-wave[63] and midazolam-induced loss of responsiveness.[64] This breakdown of cortical connectivity, rather than pharmacologic deafferentation from the environment, could underlie loss of consciousness.[65] Unconsciousness would then be characterized not by the absence but by the fragmentation of cortical processing.

Although the mechanism of "binding" (i.e., creating the unity of perception) is uncertain, synchronicity of neuronal activity in the 40- to 90-Hz range across functionally connected cortical areas (commonly referred to as 40-Hz- or γ-rhythm) is a viable candidate. Animal[66,67] and human[68] data implicate activity in the γ-band throughout the cortex as a network-level target of general anesthetics. Anesthetic actions on cortical information processing probably consist not merely of suppression of responses but of reduced complexity and variability reflected counterintuitively in the increased reliability and precision of evoked responses.[69,70]

A consistent and intriguing observation has been that anesthetics suppress descending more than ascending neural connectivity.[59,71] Within the framework of predictive coding,[72] this indicates that unconsciousness is associated with a reduction in internally generated predictions more than a suppression of incoming sensory information. The molecular and cellular mechanisms underlying this effect remain undefined, but the preferential suppression by isoflurane of cortico-cortical responses in brain slices in vitro[73,74] supports a top-down mechanism wherein the anesthetic acts directly on the thalamocortical circuitry.

By contrast, "bottom-up" theories attribute changes in consciousness to anesthetic modulation of subcortical arousal nuclei. An interesting theme has emerged from this line of research. There is substantial overlap between the centers whose activity is altered during natural slow-wave sleep and the state of general anesthesia.[35,75–77] That is, many anesthetics may induce unconsciousness, at least in part, by "hijacking" neural sleep[78,79] or arousal[80] pathways.

Thalamic theories of anesthetic-induced unconsciousness[81,82] incorporate aspects of both top-down and bottom-up mechanisms, reflecting not only the intermediate position of this structure in the hierarchical organization of the brain but also the different connection patterns of "sensory relay" versus higher-order "nonspecific" thalamic nuclei.[83]

LEARNING AND MEMORY

Anterograde amnesia, one of the core desirable anesthetic end points, is achieved at lower anesthetic concentrations (~0.25 MAC) than those required for unconsciousness (~0.5 MAC). Perhaps the closest analogue in rodents to explicit memory in humans is medial temporal lobe–dependent learning of temporal and spatial sequences known as *hippocampus-dependent spatial learning*. Other learning paradigms, such as fear conditioning to tone, are by contrast independent of the hippocampus. Spatial learning can be tested by a variety of experimental paradigms, including fear conditioning to context (Fig. 19.5). Isoflurane and the nonimmobilizer F6 both inhibit hippocampus-dependent learning at about half the concentration necessary for disrupting hippocampus-independent learning.[84] Similarly, anesthetic concentrations that inhibit explicit memory in humans (memory that can be explicitly recalled as opposed to motor learning, classical conditioning, and so on) are similarly lower than concentrations that impair implicit memory (not subject to willful recollection).[85] Taken together, these findings implicate effects on function of the medial temporal lobe, including the hippocampus, in the suppression of explicit memory by anesthetics. Effects on other structures, such as the amygdala, may be relevant to anesthetic impairment of implicit or other types of memory.[86]

Because inhaled anesthetics affect multiple cellular targets even at amnesic concentrations, it is likely that anesthetic-induced amnesia arises from multiple cellular-level changes. A quantitative comparison of the degree of change in synaptic inhibition in the hippocampus produced by equiamnestic concentrations of isoflurane versus etomidate indicated that the enhancement of GABAergic inhibition can account for a substantial portion of isoflurane's effect on memory.[87] Other contributing targets may include nAChRs,[88] HCN1 channels,[89] and excitatory glutamatergic synapses,[90] Conversely, it is also likely that suppression of learning and memory by drugs known to have different receptor affinities share common mechanisms at some level of integration. For example, θ-rhythms (4-12 Hz) are clearly important for hippocampus-dependent learning and memory.[91] Benzodiazepines[92] and cannabinoids[93] slow and suppress hippocampal θ-rhythms in proportion to their ability to impair hippocampus-dependent learning. Isoflurane and the nonimmobilizer F6 have comparable effects on θ-rhythms at amnesic concentrations while having different receptor-level profiles and opposite effects on sedation.[94] Thus alterations in neuronal synchrony may

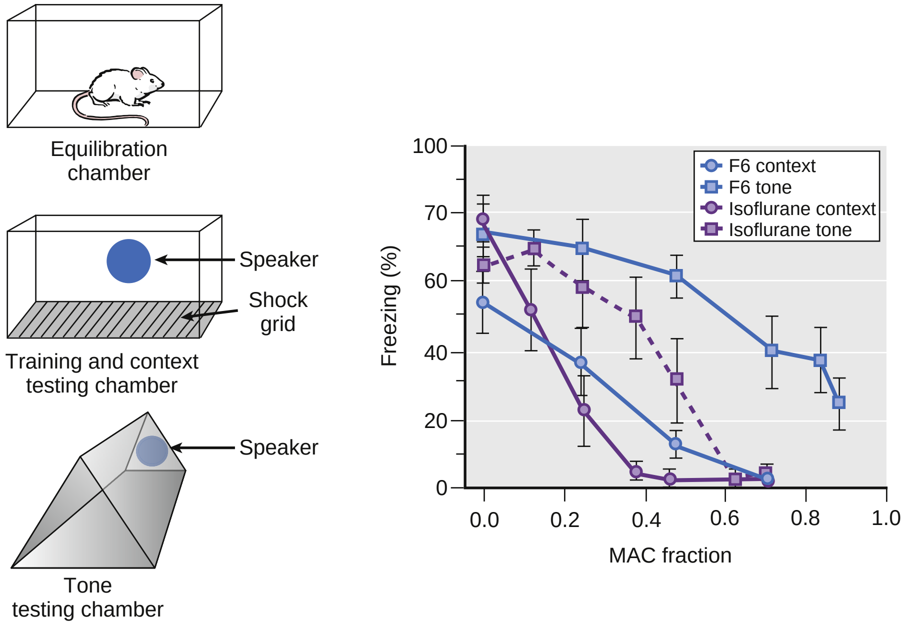

Fig. 19.5 Differential sensitivity of different types of learning to anesthetics and nonimmobilizers. Freezing in anticipation of a noxious stimulus is a measure of learning in rats; less freezing indicates less learning. *Left,* the learning protocol involves preequilibration of rats in the equilibration chamber to isoflurane or the nonimmobilizer *F6* at the desired concentration before placement into the training chamber. For testing of memory to context, the training and test chamber are identical. For testing of memory to tone, training and testing take place in different chambers. *Right,* hippocampus-dependent learning (fear conditioning to context, *closed symbols*) is inhibited by isoflurane *(purple circles)* at lower concentrations than hippocampus-independent learning (fear conditioning to tone, *purple squares*). This differential sensitivity is mirrored by the nonimmobilizer F6 (*blue circles* and *blue squares* for context and tone, respectively). (*Left panel* adapted with permission from Eger EI 2nd, Xing Y, Pearce R, et al. Isoflurane antagonizes the capacity of flurothyl or 1,2-dichlorohexafluorocyclobutane to impair fear conditioning to context and tone. *Anesth Analg*. 2003;96:1010–1018; *right panel* data points reconstructed from Dutton RC, Maurer AJ, Sonner JM, et al. Short-term memory resists the depressant effect of the nonimmobilizer 1-2-dichlorohexafluorocyclobutane (2N) more than long-term memory. *Anesth Analg*. 2002;94:631–639; and Dutton RC, Maurer AJ, Sonner JM, et al. The concentration of isoflurane required to suppress learning depends on the type of learning. *Anesthesiology*. 2001;94:514–519.)

provide a common network-level substrate for memory impairment. The synchronization between amygdalar and hippocampal θ-rhythms that occurs during fear memory retrieval indicates that this principle might also apply to other forms of memory and their impairment by anesthetics.[95] As with other components of the anesthetic state, the precise mechanisms of memory impairment by anesthetics and of memory itself remain to be fully elucidated.

SEDATION

Sedation (defined as a decrease in activity, alertness, arousal, and/or vigilance), which is on a behavioral continuum leading to hypnosis, is achieved at anesthetic doses similar to those that produce amnesia (<0.5 MAC). There is no clear mechanistic or clinical separation between sedation and hypnosis. By contrast, even though sedation can be difficult to separate from amnesia, for intravenous anesthetics there may be separate but overlapping substrates for these two end points.[31] The mechanisms involved in these behavioral effects are likely to resemble those of less promiscuous drugs, for which genetic approaches have been informative. An amino acid knockin mutation (H101R) in mice that renders the α_1 GABA_A receptor subunit insensitive to modulation by benzodiazepines produces resistance to the sedative and amnesic effects of benzodiazepines while maintaining other behavioral effects, among them anxiolysis.[96] The α_1 subunit is abundantly expressed in the CNS, mainly in the cortical areas and thalamus. Volatile anesthetics have qualitatively similar effects on α_1-containing GABA_A receptors (but also those containing other subunits) at low concentrations. The observation that the nonimmobilizer F6, which is devoid of sedative properties,[94] is amnesic[97] but does not modulate benzodiazepine-sensitive α_1-containing GABA_A receptors,[98,99] is compatible with a role for α_1-containing receptors in volatile anesthetic-induced sedation, because few other targets are affected at purely sedative concentrations. Possible targets for the sedative effects of the gaseous anesthetics nitrous oxide and xenon, which do not affect GABA_A receptors, include *N*-methyl-D-aspartate (NMDA) receptor antagonism[100] and K_{2P} channel activation.[101] Consistent with this distinct pharmacologic profile, nitrous oxide has strikingly different effects from those of benzodiazepines in behavioral tests aimed at evaluating sedation in mice.[102]

Recognizing that there may be more than a superficial similarity between natural sleep and anesthetic-induced sedation and hypnosis, the effects of some anesthetics apparently share natural sleep mechanisms by directly activating discrete sleep-promoting nuclei in the hypothalamus.[35] Indeed, the same neurons, or at least overlapping populations of neurons, that are activated by sleep deprivation are also activated during dexmedetomidine-induced sedation.[103] Electroencephalographic patterns during natural slow-wave sleep and anesthesia show similarities,[104] and recovery from sleep deprivation can occur under propofol[105,106] and inhalational anesthesia, supporting this concept. Anesthetic effects on other cortical[107] and subcortical structures[32] may also contribute to anesthetic-induced sedation and hypnosis.

Identification of Molecular Sites of Anesthetic Action

CRITERIA FOR IDENTIFYING SITES RELEVANT TO ANESTHESIA

Specific criteria have been proposed to evaluate the relevance of the many potential molecular targets of anesthetics.[108] These criteria include the following:

1. *Reversible alteration of target function at clinically relevant concentrations.* This criterion requires comparable in vivo and in vitro sensitivities and depends on the anesthetic end point under consideration. For example, targets involved in immobility must be sensitive to anesthetics near MAC, whereas targets mediating amnesia must be affected at a fraction of MAC. Recent evidence for persistent effects of inhaled anesthetics demonstrable in the absence of continued anesthetic exposure is challenging the notion of reversibility for certain effects.
2. *Expression of the target in appropriate anatomic locations to mediate the specific anesthetic end point.* For example, immobilization by inhaled agents appears to involve primarily actions in the spinal cord independent of actions in the brain.
3. *Concordant stereoselectivity of anesthetic effects in vivo and on the target in vitro.* Without a specific pharmacologic antagonist of anesthesia, correlation between the stereoselective actions of general anesthetics in vivo and in vitro is a useful test of pharmacologic relevance of putative molecular targets. Stereoselectivity data correlating in vivo potency and in vitro receptor actions implicate $GABA_A$ receptors as a target for the anesthetic actions of etomidate, pentobarbital, neurosteroid anesthetics, and isoflurane.
4. *Appropriate sensitivity or insensitivity to anesthetic and nonanesthetic compounds.* Anesthetic halogenated cyclobutanes together with structural analogs that do not produce anesthesia at concentrations predicted to be anesthetic by the Meyer-Overton correlation (nonimmobilizers) can be used to discriminate relevant volatile anesthetic targets in vitro. For example, the anesthetic F3 (1-chloro-1,2,2-trifluorocyclobutane), but not the structurally similar nonanesthetic F6 (1,2-dichlorohexa fluorocyclobutane), affect $GABA_A$, glycine, AMPA (α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid), kainate, and 5-HT3 receptors; and Na^+ channels, consistent with possible roles in immobility, whereas both F3 and F6 affect neuronal nicotinic, M1 muscarinic, 5-HT2C, and mGluR5 receptors, indicating that these targets are not involved in immobility. F6 is interesting in that it lacks sedative and immobilizing effects but does possess amnesic effects, hence use of the more accurate term *nonimmobilizer*, making it a useful pharmacologic tool for discriminating targets for these actions.
5. *Predictable effects of genetic manipulations targeted to putative molecular targets.* The effects of targeted deletion of specific molecules implicated as anesthetic targets (knockout mutations) or genetic engineering to introduce specific mutations that modify anesthetic sensitivity (knockin mutations) in model organisms provide powerful approaches to test the roles of putative molecular targets of anesthetic action. This approach has been particularly successful in implicating specific $GABA_A$ receptor subtypes in the effects of the GABAergic intravenous anesthetics propofol and etomidate, where single amino acid substitutions in specific receptor subtypes eliminate anesthetic effects both in vitro and in vivo.[109] Targeted mutations of putative anesthetic targets provide a bridge between in vitro observations and whole-animal experiments essential for demonstrating anesthetic end points. The existence of multiple targets and redundancy among ion channel subtypes makes this a more challenging experimental approach for inhaled anesthetics compared with intravenous anesthetics (discussed later).

PHYSICOCHEMICAL PROPERTIES OF ANESTHETIC BINDING SITES

A convergence of x-ray crystallography, molecular modeling, and structure-function studies indicates that inhaled anesthetics bind in the hydrophobic cavities formed within proteins.[22] The lipophilic (or hydrophobic) nature of these binding sites explains their adherence to the Meyer-Overton correlation. An element of amphiphilicity (possessing both polar and nonpolar characteristics) is also required for effective interaction with these cavities, as indicated by improvements in the Meyer-Overton correlation with more amphipathic solvents (possessing both hydrophobic and hydrophilic properties).[7]

FROM MODEL PROTEINS TO RECEPTORS

Identifying inhaled anesthetic binding sites on plausible target proteins is difficult because of their low-affinity interactions, the paucity of atomic resolution structures of pharmacologically relevant target proteins, and the lack of specific antagonists. Consequently most anesthetic binding sites have been identified in well-characterized model proteins for which three-dimensional atomic resolution structures—such as luciferase[110] and serum albumin[111]—are available but are not themselves relevant to anesthesia. These studies indicate that anesthetics bind in pockets with both nonpolar and polar noncovalent chemical interactions.[23,112] Binding involves weak hydrogen bond interactions with polar amino acid residues and water molecules, nonpolar van der Waals interactions, and a polarizing effect of the amphiphilic binding cavity on the relatively hydrophobic anesthetic molecules. Occupation of a site, or sites, by an anesthetic provides a plausible mechanism for alteration of receptor and ion channel function by selectively binding to a particular conformation (e.g., an open or inactivated state of an ion channel).[22] Studies of glycine, $GABA_A$, and NMDA receptors provide convincing evidence for the existence of anesthetic binding sites in critical neuronal signaling proteins.[113] It is likely that before long, high-resolution crystal structures of these receptors will be determined with inhaled anesthetic bound. However, because anesthetics act by binding only to certain transient conformational states, the relevance of necessarily static crystal structures will have to be assessed with care.

Structural studies using the more accessible prokaryotic homologues of eukaryotic ion channels have provided a powerful tool for the study of anesthetic binding sites in biologically plausible proteins. For example, both propofol and desflurane have been cocrystalized with *Gloebacter violaceus*, a bacterial homologue of eukaryotic inhibitory ligand-gated ion channels (glycine and $GABA_A$ receptors). Both anesthetics bind to a common preexisting site in the upper part of the transmembrane domain between the transmembrane segments of a single subunit (Fig. 19.6).[114] Molecular modeling based on structurally homologous proteins has also been used to identify putative anesthetic binding sites in the transmembrane domains of vertebrate $GABA_A$ and glycine receptors (Fig. 19.7). These models

suggest that different drugs may either bind in different orientations within a single amphiphilic cavity or occupy different cavities within the protein, causing similar functional effects. Refinement of these molecular models will continue to provide new insights in the molecular basis for general anesthetic action that can be experimentally tested. For example, potential sites of interaction of xenon and isoflurane with the NMDA receptor have also been identified using this approach. One site, which can contain up to three xenon atoms or one molecule of isoflurane, overlaps the known binding site for the coagonist glycine in the NR1 subunit.[115] This suggests that two chemically dissimilar inhaled anesthetics inhibit NMDA receptors by direct competitive inhibition of coagonist binding.

Molecular Targets of Inhaled Anesthetics

Ion channels have emerged as the most promising molecular targets for inhaled anesthetics. Neurotransmitter-gated ion channels—in particular $GABA_A$, glycine, and NMDA-type glutamate receptors—are leading candidates owing to their appropriate CNS distributions, essential physiologic roles in inhibitory and excitatory synaptic transmission, and sensitivities to clinically relevant concentrations of anesthetics.[22,27,108,116] Other ion channels that are sensitive to inhaled anesthetics include the hyperpolarization-activated cyclic nucleotide (HCN)-gated family of channels that give rise to pacemaker currents[116] and regulate dendritic excitability, two-pore domain (K_{2P}) "leak" K^+ channels that maintain resting membrane potential in many cells,[117,118] and voltage-gated Na^+ and Ca^{2+} channels.[116]

LIGAND-GATED ION CHANNELS

Potentiation of Inhibitory $GABA_A$ and Glycine Receptors

The ether anesthetics (including isoflurane, sevoflurane, and desflurane), the alkane anesthetic halothane, most intravenous anesthetics (including propofol, etomidate, barbiturates), and the neurosteroid anesthetics enhance $GABA_A$ and glycine receptor (GlyR) function. $GABA_A$ and GlyRs are members of the same cys-loop ligand-gated ion channel superfamily that also includes the cation-permeable nicotinic acetylcholine and $5HT_3$ receptors. $GABA_A$ receptors are the principal transmitter-gated Cl^- channels in the neocortex and allocortex, whereas GlyRs fulfill this function in the spinal cord, with some overlap in the diencephalon and brain stem. Activated receptors conduct chloride ions, driving the membrane potential toward the Cl^- equilibrium potential. Both receptors are inhibitory (except in some cases during development) because the Cl^- equilibrium potential is usually more negative than the normal resting potential. Channel opening also reduces membrane resistance and "shunts" excitatory responses. Most functional $GABA_A$ and GlyRs are heteropentamers, typically consisting of three different $GABA_A$ subunits (e.g., two α, two β, and one γ or ∂)[119] or two different GlyR subunits (three α and two β).[120] The subunit composition of $GABA_A$ receptors determines their physiologic and pharmacologic properties and varies between and within brain areas as well as between different compartments of individual neurons. Examples are the preferential expression of the α_5 subunit in the dendritic field of the hippocampal CA1 area (a region important for memory formation), of the α_4 subunit in the thalamus, and of the α_6 subunit in the cerebellum. Presence of a γ subunit is required for benzodiazepine modulation of $GABA_A$ receptors and can also influence modulation by inhaled anesthetics. Although the molecular mechanisms of receptor modulation by inhaled anesthetics are not clear, these receptors have been key to our understanding of anesthetic-receptor interactions. Using chimeric receptor constructs between anesthetic-sensitive $GABA_A$ and insensitive GlyR subunits, specific amino acid residues in transmembrane domains 2 and 3 critical to the action of inhaled anesthetics have been identified.[121] This laid the groundwork for the construction of anesthetic-resistant $GABA_A$ receptors and the generation of transgenic mice with altered anesthetic sensitivity (discussed later).

The related cation-permeable 5-hydroxytryptamine (serotonin)-3 ($5HT_3$) receptors are similarly potentiated by volatile anesthetics.[122,123] $5HT_3$ receptors are involved with autonomic reflexes and also probably contribute to the emetogenic properties of volatile anesthetics.

Inhibition of Excitatory Acetylcholine and Glutamate Receptors

Neuronal nicotinic acetylcholine receptors (nnAChRs), like the other members of the cys-loop family, are heteropentameric ligand-gated ion channels but are cation-selective. They are composed of α and β subunits but functional homomeric receptors can be formed by certain α subunits. In the CNS, nnAChRs are localized primarily presynaptically.[124] Homomeric α_7 receptors have high permeability to Ca^{2+}, which can exceed that of NMDA receptors.[124] In contrast to $GABA_A$ and GlyRs, nnAChRs pass cations when activated and therefore depolarize the membrane potential. Receptors containing $\alpha_4\beta_2$ subunits are very sensitive to block by isoflurane.[125,126] Relevance of nnAChR block to immobilization, sedation, and unconsciousness by inhaled anesthetics is unlikely because nnAChRs are also blocked by nonimmobilizers, although it is possible that they do contribute to amnesia.

NMDA receptors are a major postsynaptic receptor subtype of inotropic receptors for glutamate, the principal excitatory neurotransmitter in the mammalian CNS.[127] Typical NMDA receptors, defined pharmacologically by their selective activation by the exogenous agonist NMDA, are heteromers consisting of an obligatory GluN1 subunit and modulatory GluN2 subunits. Channel opening requires glutamate (or another synthetic agonist such as NMDA) binding to the GluN2 subunit while the endogenous coagonist glycine binds to the GluN1 subunit. NMDA receptors also require membrane depolarization to relieve voltage-dependent block by Mg^{2+}. Depolarization is typically provided by the binding of glutamate to non-NMDA glutamate receptors (discussed later). Because of this requirement for both presynaptic transmitter release and postsynaptic depolarization, synaptic NMDA receptors function as coincidence detectors, and this characteristic is thought to be central to their role in learning and memory. NMDA receptors are also involved in the development of chronic pain, perhaps because of mechanisms similar to those underlying synaptic plasticity, and in ischemia-induced excitotoxicity by virtue of their capacity to allow entry of the ubiquitous intracellular signal Ca^{2+}. The nonhalogenated inhaled

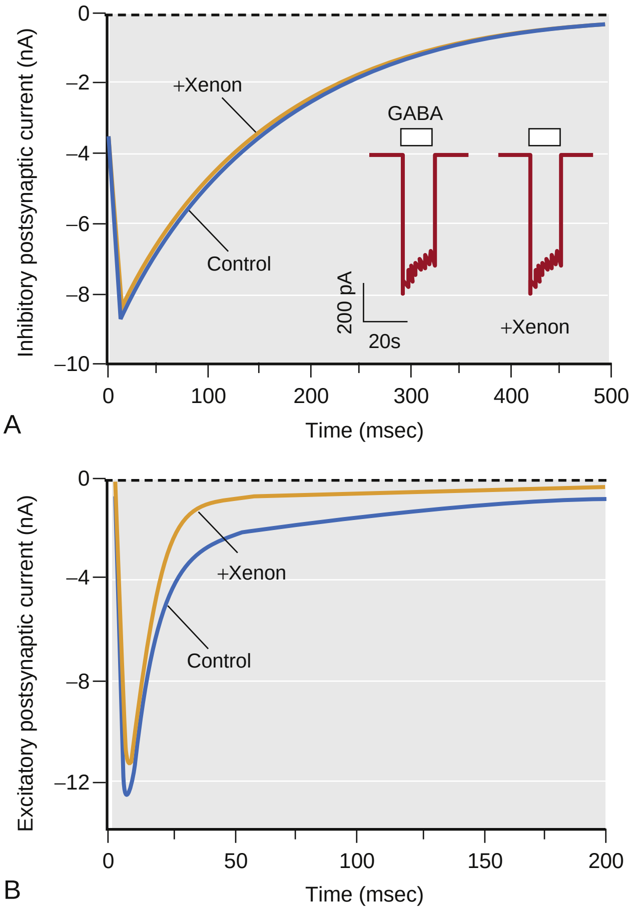

Fig. 19.8 The actions of xenon on inhibitory GABAergic and excitatory glutamatergic synapses in cultured rat hippocampal neurons. Xenon (3.4 mM, or 1 minimum alveolar concentration [MAC]) has no significant effect on the inhibitory postsynaptic current (A) but depresses the excitatory glutamatergic synaptic current, almost exclusively the slow *N*-methyl-D-aspartate receptor-mediated component of the current (B). In contrast, the principal effects of 1 MAC isoflurane are a prolongation in the inhibitory current decay and a reduction in excitatory current peak height, with little change in time course (not shown, see Fig. 19.10). (Reprinted in modified form by permission from de Sousa SLM, et al. Contrasting synaptic actions of the inhalational general anesthetics isoflurane and xenon. *Anesthesiology*. 2000;92:1055–1066.)

anesthetics xenon, nitrous oxide, and cyclopropane have minimal effects on GABA$_A$ receptors but depress excitatory glutamatergic synaptic transmission postsynaptically via NMDA glutamate receptor blockade (Fig. 19.8).[128,129] Volatile anesthetics can also inhibit isolated NMDA receptors at higher concentrations.[130] Along with presynaptic inhibition of glutamate release, this might contribute to their depression of NMDA receptor–mediated excitatory transmission.

A second class of inotropic glutamate receptors includes the non-NMDA receptors, which are subdivided into AMPA and kainate receptors based again on their sensitivities to selective exogenous agonists.[127] Inhaled anesthetics only weakly inhibit AMPA receptors; hence this action is unlikely to be important in their actions.[131] Interestingly, kainate receptors are enhanced by inhaled anesthetics, but this is unlikely to be involved in immobility because MAC is not altered in mice deficient in the GluR6 receptor subunit.[132] Most evidence suggests that the principal mechanism for depression of glutamatergic transmission by volatile anesthetics is presynaptic, with minor contributions from postsynaptic receptor blockade[133-135] (see section on "Cellular Mechanisms").

VOLTAGE-GATED AND OTHER ION CHANNELS

Volatile anesthetics have diverse effects on a wide variety of ion channels that are critically involved in their neurophysiologic, cardiovascular, and respiratory actions. A detailed understanding of these interactions is crucial to a pharmacologic description of this essential drug class.

Na$^+$ Channels

Voltage-gated Na$^+$ channels are critical to axonal conduction, synaptic integration, and neuronal excitability. In contrast to findings in invertebrate giant axons,[136] axonal conduction in small (0.1-0.2 μm) unmyelinated hippocampal axons is depressed by volatile anesthetics,[137,138] and small reductions in preterminal action potential amplitude significantly depress transmitter release and hence postsynaptic responses at a mammalian synapse.[139] Heterologously expressed mammalian voltage-gated Na$^+$ channels are sensitive to clinically relevant concentrations of volatile anesthetics. The Na$^+$ channel family consists of nine homologous pore-forming α subunits with distinct cellular and subcellular distributions.[140,141] Isoflurane and other volatile anesthetics inhibit the major mammalian Na$^+$ channel isoforms, including neuronal (Na$_v$1.2), skeletal muscle (Na$_v$1.4), cardiac (Na$_v$1.5), and peripheral (Na$_v$1.8) isoforms.[142] Volatile anesthetics but not nonimmobilizers also inhibit native neuronal and nerve terminal Na$^+$ channels,[141,143-146] lending support to the notion that Na$^+$ channel blockade contributes to the depression of synaptic neurotransmitter release.[147] In contrast, xenon has no detectable effect on Na$^+$, Ca^{2+}, or K$^+$ channels in isolated cardiomyocytes.[148] The demonstration that NaChBac, a prokaryotic homologue of voltage-gated Na$^+$ channels, is also inhibited by volatile anesthetics opens the way for structure-function studies of these channels.[145] These studies suggest that volatile anesthetics affect channel gating, probably via at least two drug binding sites.[149-151]

Ca^{2+} Channels

Multiple cellular functions depend on the tightly controlled concentration of intracellular free Ca^{2+} ($[Ca^{2+}]_i$), which is determined by the integrated activities of voltage-gated Ca^{2+} channels, capacitative Ca^{2+} channels, plasma membrane and sarcoplasmic/endoplasmic reticulum (ER) Ca^{2+}-adenosine triphosphatases (pumps), Na$^+$/Ca^{2+} exchangers, mitochondrial Ca^{2+} sequestration, and cytoplasmic Ca^{2+}-binding proteins. Alteration of any of these mechanisms can affect the many cellular processes regulated by the second-messenger actions of Ca^{2+}, including synaptic transmission, gene expression, cytotoxicity, and muscle excitation-contraction coupling. Excitable cells translate their electrical activity into action by Ca^{2+} fluxes mediated primarily by voltage-gated Ca^{2+} channels in the plasma membrane. Distinct Ca^{2+} channel subtypes are expressed in various cells and tissues, and are classified pharmacologically and functionally by the degree of depolarization required to gate the channel as low voltage–activated

(LVA; T-type) or high voltage–activated (HVA; L-, N-, R-, and P/Q-type) channels. Cloning and sequencing to identify their pore-forming α subunits has allowed molecular classification of these functionally identified channel subtypes.[141] Considerable evidence indicates that volatile anesthetics inhibit certain Ca^{2+} channel isoforms but not others.

Inhibition of presynaptic voltage-gated Ca^{2+} channels coupled to transmitter release has been proposed as a mechanism by which volatile anesthetics reduce excitatory transmission.[152,153] Indeed, N-type ($Ca_v2.2$) and P-type ($Ca_v2.1$) channels, which mediate Ca^{2+} entry coupled to neurotransmitter release, are modestly sensitive to volatile anesthetics[154,155] but not in all neuron types,[156] suggesting the importance of auxiliary subunits, posttranslational modification, or other potential modulators of anesthetic sensitivity. A modest contribution of R-type Ca^{2+} channels ($Ca_v2.3$) to anesthesia is suggested by their sensitivity to volatile anesthetics and a small increase in MAC produced by genetic deletion in mice.[157] T-type Ca^{2+} channels are particularly sensitive to volatile anesthetics[158] and nitrous oxide.[159] However, mutant mice lacking a major neuronal T-type Ca^{2+} channel isoform ($Ca_v3.1$) have normal volatile anesthetic sensitivity, although the onset of anesthesia is delayed.[160] Thus the role that inhibition of these or other Ca^{2+} channels plays in the CNS effects of inhaled anesthetics is unclear.

At higher doses, a role for Ca^{2+} channel inhibition in the negative inotropic effects of volatile anesthetics is well established. The force of myocardial contraction is determined by the magnitude of cytosolic Ca^{2+} increase after electrical excitation, the responsiveness of the contractile proteins to Ca^{2+}, and sarcomere length. Negative inotropic effects of volatile anesthetics are mediated by reductions in Ca^{2+} availability, Ca^{2+} sensitivity of the contractile proteins, and rate of cytosolic Ca^{2+} clearance. Volatile anesthetics reduce the Ca^{2+} transient and shorten action potential duration in cardiomyocytes primarily by inhibiting L-type ($Ca_v1.2$) Ca^{2+} currents, resulting in a negative inotropic effect and arrhythmogenicity.[161-163] In contrast, xenon does not depress myocardial function or inhibit L-type Ca^{2+}, Na^+, or K^+ currents in isolated cardiomyocytes.[164,165] Inhibition of trans-sarcolemmal Ca^{2+} influx through cardiac L-type Ca^{2+} channels plays a major role in the negative inotropic effects of volatile anesthetics—greatest for halothane—along with contributions from effects on myofilament Ca^{2+} sensitivity and sarcolemmal Ca^{2+} release.[162,166]

In contrast to voltage-gated Ca^{2+} channels that regulate the influx of extracellular Ca^{2+}, intracellular Ca^{2+} channels regulate Ca^{2+} release from intracellular stores, particularly the ER and sarcoplasmic reticulum (SR). These include 1,4,5-inositol triphosphate receptors (IP_3Rs), regulated by the second messenger IP_3, and ryanodine receptors (RyRs); the latter mediate the release of SR Ca^{2+}, which is critical to excitation-contraction coupling in muscle. Volatile anesthetic–induced Ca^{2+} leak occurs by effects on both IP_3R and RyR channels, which leads to depletion of intracellular Ca^{2+} stores from the SR and ER. In brain, volatile anesthetic activation of IP_3Rs has been proposed as a mechanism for anesthetic neurotoxicity.[167] This blunts changes in intracellular Ca^{2+} in response to stimulation and contributes to the smooth muscle–relaxing properties of volatile anesthetics that underlie bronchodilation and vasodilation.[168] Malignant hyperthermia is a pharmacogenetic disorder that manifests as a potentially fatal hypermetabolic crisis triggered by volatile anesthetics, particularly halothane. It is often associated with mutations in RyR1 and the physically associated L-type Ca^{2+} channel ($Ca_v1.1$), which functions as the voltage sensor.[169] Volatile anesthetics activate the mutated RyRs, resulting in uncontrolled intracellular Ca^{2+} release from the SR, muscle contraction, and hypermetabolic activity.[170]

K^+, HCN, and TRP Channels

Potassium (K^+) channels are members of an extremely diverse ion channel family noted for their varied modes of activation. They regulate electrical excitability, muscle contractility, and neurotransmitter release. They are important in determining input resistance and in driving repolarization after action potentials; thus they determine excitability and action potential duration. Given the large diversity in K^+ channel structure, function, and anesthetic sensitivity, it is not surprising that there is considerable diversity in their sensitivity and response to inhaled anesthetics,[171] from relatively insensitive (voltage-gated K^+ channels $K_v1.1$, K_v3)[172] to sensitive (some members of the K_{2P} family), resulting in either inhibition, activation, or no effect on K^+ currents.

Volatile anesthetic activation of certain "leak" K^+ channels was first observed in the snail *Lymnaea*,[173] although the molecular identity of the affected ion channels was unknown. Activation of K_{2P} channels by volatile and gaseous anesthetics—including xenon, nitrous oxide, and cyclopropane—was subsequently observed in mammals.[118] Increased K^+ conductance can hyperpolarize neurons, reducing responsiveness to excitatory synaptic input and possibly altering network synchrony. Targeted deletion of the TASK-1, TASK-3, and TREK-1 K_{2P} channels in mice reduces sensitivity to immobilization by volatile anesthetics in an agent-specific manner, implicating these channels as contributory anesthetic targets in vivo.[44-47] The K^+ channel TREK-1 also contributes to the neuroprotective effects of xenon[174] and sevoflurane.[175]

Progress has recently been made in identifying anesthetic binding sites to K^+ channels using photoaffinity labeling, which has identified a sevoflurane binding site in the $K_v1.2$ channel; this is widely expressed in brain and positively modulated by volatile anesthetics.[176] Molecular modeling has also been used to identify likely binding sites in K_{2P} channels.[177]

The recognition that inherited channelopathies are arrhythmogenic and constitute an important contributor to sudden cardiac death,[178] particularly in young children,[179] highlights the importance of analyzing anesthetic modulation of cardiac ion channels. Recombinant hERG (human ether-a-go-go–related) channels are moderately inhibited by halothane, and their depression likely contributes to arrhythmogenic effects of volatile anesthetics[162,180]; they are also involved in acquired (drug-induced) and inherited long QT syndrome. Cardiac inward-rectifying (K_{IR}), voltage-gated (K_v), and Ca^{2+}-activated K^+ channels are generally relatively insensitive to clinical concentrations of volatile anesthetics and xenon.[162,164,181] In contrast, volatile anesthetics and xenon activate cardiac mitochondrial and sarcolemmal K_{ATP} channels,[182] which might contribute to anesthetic preconditioning to cardiac ischemia. Direct electrophysiologic effects of anesthetics with preconditioning properties have been demonstrated on both mitochondrial and sarcolemmal K_{ATP} channels, although the precise mechanisms remain to be clarified. The large conductance (BK) mitochondrial K^+ channel Slick of the *Slo2* gene family has been shown to be important for volatile anesthetic preconditioning in vivo.[183]

Volatile anesthetics also inhibit HCN pacemaker channels, reducing the rate of rise of pacemaker potentials and the bursting frequency of certain neurons that show autorhythmicity. They decrease the I_h conductance in neurons[184] and modulate recombinant HCN1 and HCN2 channel isoforms at clinically relevant concentrations.[185] Because HCN channels contribute to resting membrane potential, control action potential ring, dendritic integration, neuronal automaticity, and temporal summation, and also determine periodicity and synchronization of oscillations in many neuronal networks,[186] anesthetic modulation of these channels could play an important role in anesthetic effects on neuronal integrative functions. Selective knockout of HCN1 in mouse forebrain shows a role for these channels in the amnestic and hypnotic but not immobilizing effects of volatile anesthetics.[89]

INTRACELLULAR SIGNALING MECHANISMS

Cell signaling mechanisms are critical to all phases of organ and cellular function, which has made them attractive targets for producing the broad effects of general anesthetics on multiple organs. Anesthetics have complex actions on intracellular cell signaling pathways, which include processes downstream from cell surface receptors and ion channels, including effects on second messengers, protein phosphorylation pathways, and other regulatory mechanisms.[187]

G-Protein–Coupled Receptors

A variety of signals—including hormones, neurotransmitters, cytokines, pheromones, odorants, and photons—produce their intracellular actions by interactions with metabotropic receptors that activate heterotrimeric guanine nucleotide–binding proteins (G proteins). In contrast to inotropic receptors that directly couple to ion-selective channels, G proteins act as indirect molecular switches to relay information from activated plasma membrane receptors to appropriate intracellular targets.

Heterotrimeric G proteins consist of a large α-subunit and a smaller β/γ-subunit dimer, each expressed as multiple isoforms with distinct properties and downstream targets. G proteins regulate a plethora of downstream effectors to control the levels of cytosolic second messengers such as Ca^{2+}, cyclic adenosine monophosphate, and inositol triphosphate. These, in turn, regulate effector proteins such as ion channels and enzymes, either directly or via second messenger–regulated protein phosphorylation pathways. Ca^{2+} is a ubiquitous second messenger that regulates a number of downstream effectors, often mediated by the multifunctional Ca^{2+}-binding protein calmodulin. As volatile anesthetics have profound effects on intracellular Ca^{2+} concentrations via their effects on both plasma membrane and intracellular Ca^{2+} channels, transporters, and exchangers (see the section on ion channels earlier), many of the downstream effects of anesthetics are ultimately mediated by changes in the second-messenger actions of Ca^{2+}.

Drugs that act through G protein–coupled receptors (GPCRs) such as agonists for μ-opioid and α_2-adrenergic receptors can affect anesthetic sensitivity (reduce MAC). Inhaled anesthetics can also directly affect signaling via GPCRs.[188] For example, volatile anesthetics activate multiple olfactory GPCRs in the rat in vivo in a receptor- and agent-selective manner.[189] Analogous effects on related GPCRs more relevant to critical anesthetic end points are possible but remain to be demonstrated. The observation that both volatile anesthetics and nonimmobilizers inhibit mGluR5 glutamate receptors, 5-HT_{2A} serotonin receptors, and muscarinic acetylcholine receptors suggests that these GPCR effects do not contribute to anesthetic immobilization.[190-192]

Protein Phosphorylation

Phosphorylation of proteins on specific serine, threonine, or tyrosine hydroxyl groups, a posttranslational modification involved in the regulation of many anesthetic-sensitive receptors and ion channels, is pivotal to synaptic plasticity (e.g., long-term potentiation [LTP]). Phosphorylation is controlled by the balance of activity between protein kinases and phosphatases, several of which are plausible anesthetic targets. The protein kinase C (PKC) family of multifunctional protein kinases is activated by the lipid-signaling molecule diacylglycerol and is involved in the regulation of many ion channels and receptors. Halothane[193] and sevoflurane[194] enhance the activity of some PKC isoforms and stimulate phosphorylation of specific PKC substrates. Structural studies have identified a potential binding site in the diacylglycerol binding domain of PKCδ, consistent with the ability of certain anesthetics to mimic this natural regulator by binding to the activating site.[195] A specific role for a direct pharmacologically relevant effect related to general anesthesia mediated by anesthetic activation of PKC or of any other kinase has yet to be demonstrated. Intrathecal injection of isoform-specific inhibitors of PKC does not affect sensitivity to halothane in vivo.[196] Knockout mice lacking the PKCγ isoform show normal sensitivity to halothane and desflurane while isoflurane MAC was increased,[197] suggesting that PKC is not critical to volatile anesthetic immobilization.

An important role for effects of volatile anesthetics and xenon on cell signaling mechanisms has been discovered for anesthetic-induced preconditioning in the heart and brain against ischemic damage.[198-202] Anesthetic-induced and ischemic cardiac preconditioning share critical signaling mechanisms, including activation of multiple GPCRs (e.g., adenosine, opioid, adrenergic) and protein kinases (e.g., src kinase, PKCδ, PKCε, Akt, mitogen-activated protein kinases [MAPKs]), and their downstream targets, particularly sarcolemmal and/or mitochondrial K_{ATP} channels, possibly initiated by changes in reactive oxygen species as the critical second messenger.[203,204] Volatile anesthetics and xenon share cardioprotective and neuroprotective effects involving these signaling pathways.[202,205]

The effects of anesthetics on the phosphorylation of individual residues in specific substrates can be studied using phosphorylation state–specific antibodies that are able to detect the phosphorylated forms of kinase substrates. A comparison of the effects of three mechanistically diverse anesthetics (isoflurane, propofol, and ketamine) on critical intracellular protein phosphorylation signaling pathways that are known to integrate multiple second messenger systems reveals both shared and agent-specific actions in vivo.[206] All three anesthetics reduce phosphorylation of activating sites on NMDA and AMPA glutamate receptors and of the downstream extracellular signal-regulated kinase ERK2, all of which are known to be involved in synaptic plasticity, consistent with depression of normal glutamatergic synaptic transmission in the anesthetized mouse cerebral cortex. These effects are somewhat selective in that several other protein kinase A (PKA) substrates examined are not affected, indicating substrate-specific effects rather than a general inhibition of PKA activity.[207] Additional studies will be required to determine which anesthetic effects on kinase pathways represent direct effects, as occurs with PKC, and which are indirect because of anesthetic-induced alterations in signaling molecules known to regulate protein kinase and phosphatase activity such as Ca^{2+} and other second messengers.

Gene Expression

The ability of general anesthetics to alter gene expression in the brain was first observed for the highly reactive immediate early genes *c-fos* and *c-jun*.[208] Anesthetic effects on gene expression have since been observed for multiple anesthetics and organs.[209] In the hippocampus of aged rats, changes in gene expression persisted for up to 2 days in rats exposed to isoflurane and nitrous oxide,[210] and changes in protein expression have been observed 3 days after exposure to desflurane.[211] The significance of these changes in gene and protein expression persisting after recovery from the classic signs of anesthesia remains to be established (see review[212]). Recent findings suggest that certain anesthetic effects are mediated by epigenetic mechanisms involving specific posttranslational modifications of DNA-binding histone proteins by acetylase and deacetylase enzymes. For example, exposure of neonatal rats to general anesthesia led to reduced histone 3 acetylation and delayed cognitive deficits that could be reversed by a histone deacetylase inhibitor.[213]

Cellular Mechanisms

NEURONAL EXCITABILITY

Neuronal excitability is determined by resting membrane potential, threshold for action potential initiation, and input resistance (an indication of overall channel activity). Considerable diversity exists for each of these factors in different types of neurons, and membrane properties differ not only between neurons but also between compartments (e.g., soma versus dendrite). Moreover, anesthetic effects vary with the state of the individual neuron—that is, whether it is hyperpolarized or depolarized, stimulated by synaptic inputs, or quiescent. Therefore results obtained using model systems or reduced preparations (e.g. cultured neurons and brain slices) incompletely reflect anesthetic effects in vivo. Nevertheless much valuable information has been obtained using these approaches because they allow changes in neuronal activity to be attributed to specific cellular and molecular targets.

The intrinsic excitability of spinal motoneurons was reported to be little affected by halothane,[214] but changes in hippocampal pyramidal neuron excitability were shown to be substantial and complex. Threshold can be increased or decreased, and regional differences and dose-dependent effects on firing patterns have been observed.[215,216] Neurons in the ventral-posterior nucleus of the thalamus (possibly thalamic relay neurons) hyperpolarize in the presence of isoflurane and are less likely to fire action potentials because of a decrease in input resistance (increased shunting)—an effect that has been attributed to increased K^+ conductance.[217] Similar effects are observed in hypoglossal motoneurons and neurons from the locus coeruleus, where a TASK-type K_{2P} channel has been causally implicated.[218]

$GABA_A$ receptors located at extrasynaptic sites can also influence excitability by increasing membrane conductance and thereby "shunting" excitatory currents. These receptors have a high affinity for GABA; they are continually exposed to low ambient GABA concentrations and desensitize slowly.[219] Their importance to anesthesia, however, may hinge on exactly what these ambient concentrations are.[220] Tonic current in hippocampal pyramidal neurons arises primarily from α_5 subunit–containing $GABA_A$ receptors, which are highly sensitive to etomidate, propofol, midazolam, and isoflurane.[221-224] Thus they provide a potential substrate for the amnesic properties of anesthetics. These same receptors also contribute to slow phasic (synaptic) currents, which are produced by spillover of GABA from synapses.[225] Their slow time course and location, matching those of synaptic NMDA receptors, place them in an ideal position to modulate synaptic plasticity. Indeed, reducing or eliminating α_5-$GABA_A$ receptors by pharmacologic or genetic means attenuates the amnestic properties of the $GABA_A$ receptor-selective anesthetic etomidate. However, since elimination of α_5-$GABA_A$ receptors from pyramidal neurons does not reproduce this effect,[226] modulation of other cell types (interneurons or glia) may also play a role in anesthetic-induced amnesia and other anesthetic end points.

PRESYNAPTIC VERSUS POSTSYNAPTIC EFFECTS ON SYNAPTIC TRANSMISSION

General anesthetics have potent and specific effects on synaptic transmission, including presynaptic actions (by altering transmitter release) and postsynaptic actions (by altering the postsynaptic responses of neurons to specific transmitters). The relative contributions of presynaptic compared with postsynaptic anesthetic effects on synaptic transmission have been difficult to resolve, probably because the effects are transmitter- and synapse-specific. The net effect of anesthetics on synaptic transmission is determined by the relative magnitude and direction of both their presynaptic and postsynaptic effects. The general effects of inhaled anesthetics are to increase inhibitory synaptic transmission and to inhibit excitatory synaptic transmission (Fig. 19.9).

Fig. 19.9 Synaptic and extrasynaptic γ-aminobutyric acid (*GABA*$_A$) receptors are targets for inhaled anesthetics. (A) On binding of GABA to the GABA$_A$ receptor, its chloride-permeable channel opens, usually leading to hyperpolarization. Volatile anesthetics have a relatively low potency but high efficacy at synaptic GABA$_A$ receptors and a high potency and low efficacy at extrasynaptic GABA$_A$ receptors. (B) General anesthetics prolong channel opening and increase postsynaptic inhibition. The cartoon illustrates the prolongation of miniature inhibitory synaptic currents by the slowing of current decay. (C) A pentameric GABA$_A$ receptor complex in the lipid bilayer membrane *(left),* with a blowup of a single subunit showing the location of residues critical to anesthetic efficacy in the second and third transmembrane domains *(right).* (D) A tonic inhibitory conductance is revealed by the application of a GABA$_A$ receptor antagonist (bicuculline or picrotoxin), as shown by the upward shift in the baseline current. Anesthetics and benzodiazepines increase the tonic conductance, as indicated by the inward shift in the current. (Modified from Hemmings HC Jr, Akabas MH, Goldstein PA, et al. Emerging molecular mechanisms of general anesthetic action. *Trends Pharmacol Sci*. 2005;26:503–510.)

Excitatory synaptic excitation is generally decreased by volatile anesthetics (Fig. 19.10). Experiments in various slice preparations indicate that reduced excitation is primarily caused by presynaptic mechanisms.[87,133,214,227-229] A postsynaptic mechanism is also involved because the response to directly applied glutamate is reduced to some degree.[229-231] Volatile anesthetics have inconsistent effects on cloned AMPA or NMDA glutamate receptors, but they potentiate kainite receptors,[115,129,232,233] consistent with a predominantly presynaptic mechanism for glutamatergic synapses. By contrast, the effects of the nonhalogenated inhaled anesthetics (xenon, nitrous oxide, cyclopropane) appear to be mediated primarily by inhibition of postsynaptic NMDA receptors (discussed earlier). Under some circumstances, such as in patients with defects in mitochondrial complex 1[234] and in mice carrying mutations in mitochondrial complex 1,[235] inhaled agents suppress glutamate release by interfering with the energy-intensive glutamate recycling pathways,[236] thereby leading to extreme anesthetic sensitivity. Recent evidence from conditional knockout mice indicates this mechanism may contribute to various end points even in nonpathogenic states.[237]

Augmentation of GABAergic inhibition by most general anesthetics is mediated by both presynaptic and postsynaptic mechanisms. Enhancement of postsynaptic and extrasynaptic $GABA_A$ receptors is well recognized.[116] Volatile anesthetics increase spontaneous GABA release and inhibitory postsynaptic current (IPSC) frequency[238-242]—that is, their presynaptic effects at GABAergic terminals are distinct from those at glutamatergic synapses.

The mechanisms for the presynaptic effects of inhaled anesthetics, like those for their postsynaptic effects, are complex and involve multiple targets. Although a synapse-specific contribution of presynaptic Ca^{2+} channels is likely,[243] presynaptic Na^{+} channels are more sensitive than the Ca^{2+} channels coupled to glutamate release. This finding is consistent with observations that the predominant Ca^{2+} channel coupled to neurotransmitter release at hippocampal glutamatergic synapses (P/Q-type) is insensitive to isoflurane.[156] Other presynaptic mechanisms have been proposed, including actions on the vesicle fusion process, as demonstrated in the model organism *Caenorhabditis elegans*.[244,245] However, isoflurane effects on exocytosis in rat hippocampal neurons occur primarily upstream of vesicle fusion.[139,246]

Simple Circuits and Complex Networks

SIMPLE CIRCUIT PHENOMENA

The development of a mechanistic understanding of phenomena involving complex circuits has been greatly facilitated by the study of anatomically reduced (in vitro) or physiologically simplified (in vivo) preparations complemented by computer simulations (in silico). These approaches are essential for integrating reductionist observations of the multiple molecular effects of anesthetics into functional models relevant to behavioral end points. Anesthetic effects have been studied in acute brain slice preparations from various regions of the CNS (hippocampus, amygdala, cortex, thalamus, brain stem, and spinal cord)—most often from rodents. Brain slices preserve native connections but usually lack natural inputs and outputs. Slices from developing mammalian brain can also be cultured in vitro. These "organotypic slice cultures" preserve a high degree of synaptic connectivity and display spontaneous network activity, typically absent from "acute slices." Simplified in vivo preparations involve phenomena (typically evoked responses) with *relatively* well-understood circuitry. Computer models and simulations can assist in generating hypotheses for experimental testing and developing hypotheses based on experimental data.

Synaptic Plasticity

Paired-pulse depression and paired-pulse facilitation are examples of short-term plasticity in response to external stimulation. Synaptic inhibition is prolonged by volatile anesthetics in vivo[247] and in vitro,[248] in general agreement with the notion that anesthetics enhance functional inhibition in the CNS. Enhancement of paired-pulse facilitation has been attributed to the presynaptic depressant effect of volatile agents (Fig. 19.11).[133,228]

LTP, a cellular model of learning and memory, is a use-dependent strengthening of glutamatergic excitatory synaptic connections. Volatile anesthetic effects on LTP depend on the experimental preparation. Halothane, enflurane, and isoflurane do not block LTP induction in vivo, whereas ketamine and the NMDA antagonist CPP do.[247,249] By contrast, isoflurane blocks LTP in the hippocampal slice by enhancing $GABA_A$ receptor–mediated inhibition (Fig. 19.12)[250] or blocking neuronal nicotinic receptors,[88] Long-term depression, a use-dependent weakening of excitatory connections that is effectively a homeostatic counterpart of LTP, is also blocked by isoflurane in vitro.[250] The discrepancy between findings in vivo and in vitro remains unexplained.

Spontaneously Active Circuits

Spontaneous neuronal activity is decreased by volatile anesthetics both in vivo and in cortical brain slices. This effect is largely $GABA_A$ receptor-dependent and marked even at low sedative concentrations.[107] Because the cortical brain slices lack subcortical input, these results suggest that volatile anesthetics can cause some effects (e.g., sedation)

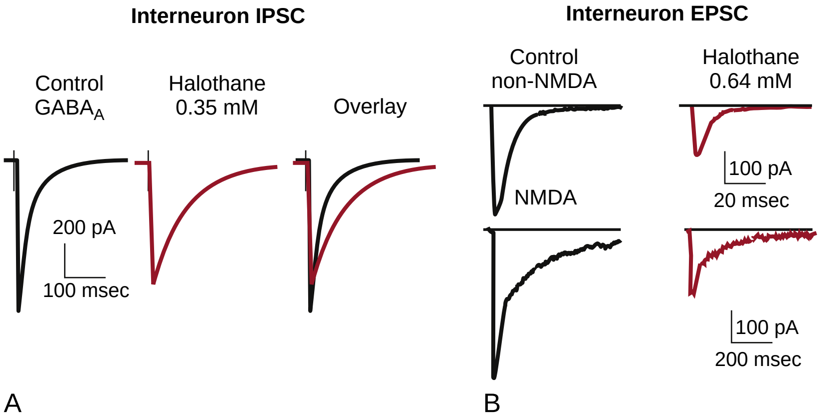

Fig. 19.10 Halogenated anesthetics enhance inhibitory and depress excitatory synaptic transmission. Halothane slows the decay of $GABA_A$ receptor–mediated inhibitory postsynaptic currents *(IPSCs)* (A) and depresses the amplitude of glutamatergic excitatory postsynaptic currents *(EPSCs)* without affecting the decay (B) in hippocampal interneurons. ([A] Redrawn with permission from Nishikawa K, MacIver MB. Membrane and synaptic actions of halothane on rat hippocampal pyramidal neurons and inhibitory interneurons. *J Neurosci*. 2000;20:5915–5923. via direct cortical action. However, changes in raw neuronal firing rates do not provide a precise quantitative measure of higher cognitive function, which is better reflected by the relationship of firing patterns to the strength and phase of ongoing cortical rhythms (see next section). Anesthetic effects have also been tested on the circuitry underlying locomotion, a well-studied central pattern generator. Effects of isoflurane on in vitro lamprey and rat spinal cord preparations support the spinal cord as the primary target for volatile anesthetic–induced immobility.[251,252]

RHYTHMS AND SIMULATIONS

The brain perpetually generates complex electrical rhythms (oscillations in extracellular field potentials) that range in frequency from fractions to hundreds of Hertz (Hz; cycles per second), as recorded on the surface of the scalp as the electroencephalogram (EEG; the higher-frequency oscillations cannot be resolved in surface recordings). All oscillations are behavioral state–dependent and multiple oscillations coexist throughout the sleep-wake cycle. Lower-frequency rhythms allow for integration over longer time periods and typically engage larger areas of the brain. By contrast, higher-frequency rhythms allow for higher temporal resolution on local scales. Cross-frequency modulation allows for integration of both aspects of information processing. Although their physiologic roles are not clear, brain rhythms reflect, subserve, and/or constitute fundamental higher-order processing such that their modulation by anesthetics is of great interest. The current nomenclature of brain rhythms reflects historical conventions and is not based on underlying mechanisms.

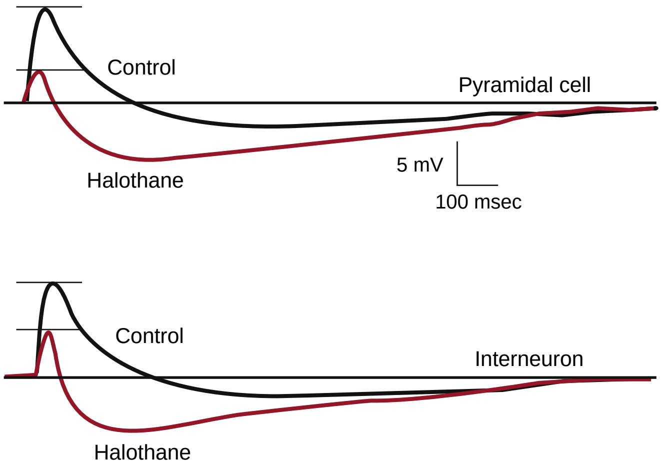

Fig. 19.11 Anesthetics affect excitation and inhibition simultaneously in opposite directions. Halothane depresses the excitatory depolarization and augments the inhibitory hyperpolarization in both hippocampal pyramidal cells and interneurons. The net result will depend on the underlying neuronal state as well as the neuronal network and its function. (Redrawn with permission form Nishikawa K, MacIver MB. Membrane and synaptic actions of halothane on rat hippocampal pyramidal neurons and inhibitory interneurons. *J Neurosci*. 2000;20:5915–5923.)

δ-Rhythms and Other Slow Rhythms

Oscillations with EEG frequencies from 1.5 to 4 Hz are generally referred to as δ-rhythms, and these oscillations are characteristic of deep sleep and are commonly observed under general anesthesia. Even slower rhythms (below 1 Hz) occur during non–rapid eye movement (NREM) sleep and appear at loss of consciousness induced by propofol[253] and sevoflurane.[254] During natural NREM sleep, δ-rhythms and sleep spindles are phase related to a slower oscillation, suggesting functional interaction.[255] Paroxysmal spindle-like waxing and waning oscillations overriding slower rhythms are also present in the cortical EEG under anesthesia. A change in δ-α phase relationships has been proposed as a "signature" of propofol-induced unconsciousness,[256] but how this comes about, whether similar changes occur for a wider range of anesthetics, and the underlying physiology and functional significance are unknown.

θ-Rhythms

θ-Rhythms, present in various cortical structures but most prominent in the hippocampus, are thought to signal the "online state." They are associated with sensorimotor and

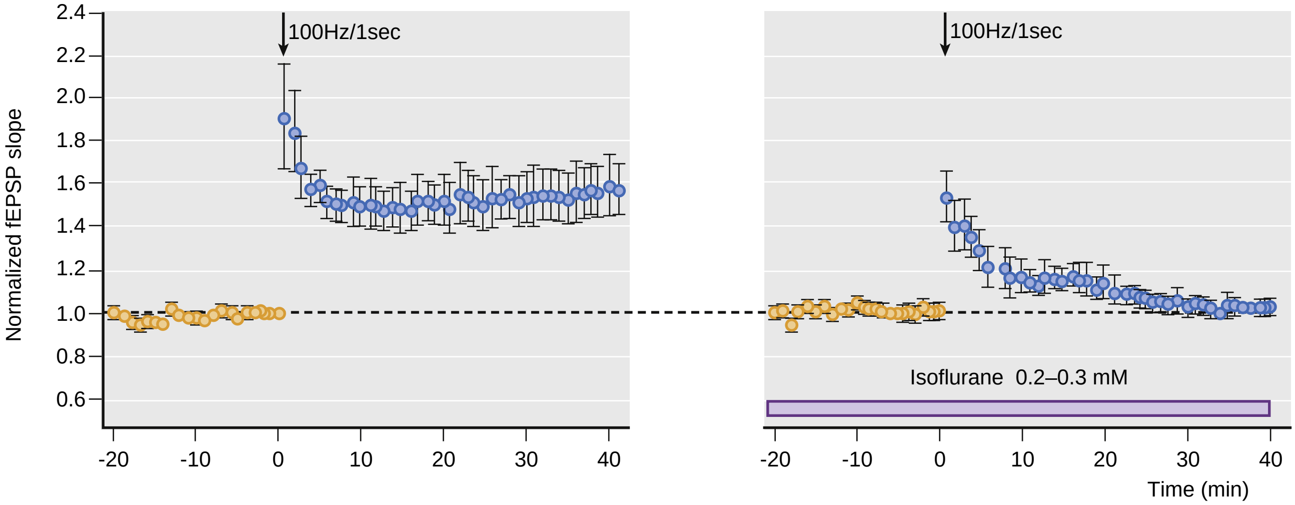

Fig. 19.12 Isoflurane blocks the induction of synaptic plasticity in vitro (a model of learning and memory). Long-term potentiation (an increase in synaptic strength), indicated by the increase in normalized excitatory postsynaptic potential *(EPSP)* slope, in hippocampal slices evoked by tetanic stimulation of excitatory synapses is blocked by 0.2 to 0.3 mM isoflurane. (Redrawn with permission from Simon W, Hapfelmeier G, Kochs E, et al. Isoflurane blocks synaptic plasticity in the mouse hippocampus. *Anesthesiology*. 2001;94:1058–1065.)

mnemonic functions during waking behavior.[257] One component of the θ-rhythm (type I or atropine-resistant) can be affected by amnestic concentrations of isoflurane as well as by the amnestic nonimmobilizer F6,[94] indicating a potential network-level signature effect for anesthetic-induced amnesia. Type II θ-rhythm (atropine-sensitive) can be evoked under anesthesia and is slowed and potentiated by halothane.[258] Interestingly, this halothane-induced oscillation disappears in TASK-3 knockout mice.[46]

γ-Rhythms

This designation includes an extremely broad and probably functionally and mechanistically heterogeneous spectrum of rhythms. It is frequently subdivided into slow γ (30-50 Hz; i.e., the spectrum above β-rhythms); γ (50-90 Hz), and fast-, ultra-γ, or ε-rhythms (>90 and up to hundreds of Hz). Fast $GABA_A$ ergic synaptic inhibition and the intrinsic resonant properties of neurons play important roles in γ-physiology, making these obvious candidates for anesthetic modulation. Isoflurane slows the frequency of evoked γ-oscillations (30-90 Hz, also known as "40-Hz rhythms") in humans.[259,260] Studies of γ-oscillations in vitro suggest that their frequency depends on the time constant of decay of $GABA_A$ receptor–mediated synaptic currents in inhibitory networks.[261] Isoflurane slows γ-rhythms in hippocampal[262] and neocortical slices[263] to a comparable degree as it does in humans,[259] providing a tentative link between receptor and circuit-level effects. However, the interaction between anesthetics and behaviorally relevant network effects is likely to be complex because flash-evoked γ-oscillations in the primary visual cortex are not affected by inhaled agents,[67] whereas feedback information transfer at γ-frequencies between the visual and frontal cortices is disrupted.[59,67] Moreover, many brain rhythms are interlinked (e.g., θ-rhythm modulates γ-oscillations (θ−γ nesting). The nature of their modulation by anesthetics as well as its relevance are far from clear.

Models and Simulations

On the macroscopic scale, computer simulations can provide an integrated picture of modulation of dynamic neuronal and network activity. "Bottom-up" neuron-by-neuron approaches are based on computational models of individual neurons, known *anesthetic effects* on intrinsic and synaptic membrane conductances, and simple network models. Computer simulations of anesthetic effects on integrated outputs can thereby be generated (e.g., the ring of pacemaker neurons).[264] These models obviously rely on the accuracy of the derived characteristics of real neurons and networks as well as knowledge of the effects of anesthetics; the scale of simulations is limited by the complexity of its elements.[265] An alternative is a "top-down" approach, such as mean-field modeling, in which molecular and cellular individual accuracy detail is sacrificed in favor of global dynamics. For example, global cortical phenomena, such as anesthetic-induced seizures, have been modeled as phase transitions based on mean interactions between populations of averaged neurons (analogous to the EEG signal that also averages the signals of neuronal populations).[266] This approach can be extended to other global cortical phenomena such as consciousness.[267] Neuronal modeling and computer simulations may gain importance in the future as bridges between theoretical and experimental studies of anesthesia.

Research Strategies for the Future

The search for anesthetic mechanisms is driven by advances in the basic sciences. Some strategies that should facilitate understanding of anesthetic mechanisms include use of agonists or antagonists in vivo, nonanesthetics or nonimmobilizers, high-resolution imaging of the functioning brain, transgenic animals, and the application of the latest techniques of molecular genetics.

PHARMACOLOGIC APPROACHES

Agonists, Antagonists, and Experimental Anesthetics

Use of receptor-specific agonists and antagonists provides a pharmacologic method for bridging in vitro with in vivo studies. In this approach, a receptor may be tested for its contribution to a specific end point (e.g., immobility) according to the criteria presented earlier. This approach was used to exclude an important role for NMDA receptor block in the immobilizing action of volatile anesthetics but did not yield conclusive results for the roles of $GABA_A$ and GlyR for immobilization,[267,268] probably owing to the intricacies of drug-receptor interactions on different levels of integration in complex networks like the spinal cord. A complementary pharmacologic approach using experimental anesthetics that inhibit NMDA receptors in vitro with different potencies supports the conclusion that NMDA receptor blockade does not contribute significantly to immobility by conventional volatile anesthetics.[269] Refinement of this strategy involves the anatomically discrete application of drugs to nuclei with known function. For example, the tuberomammillary nucleus (part of the endogenous sleep pathway) mediates the sedative component of anesthesia for some intravenous anesthetics (e.g., propofol).[35] A discrete site of general anesthetic action for GABAergic drugs in the mesopontine tegmentum has also been proposed based on this strategy.[33,34] However, these approaches suffer from the fact that, invariably, high concentrations of drugs have to be injected locally to observe pharmacologic effects (because of rapid redistribution), so that such observations need to be substantiated using more sophisticated approaches, such as genetic manipulations (see later).

Nonimmobilizers

Nonimmobilizers are compounds with physicochemical characteristics similar to those of conventional inhaled anesthetics, but their predicted anesthetizing concentrations (based on their lipid solubility and the Meyer-Overton correlation [MAC_{pred}]) do not induce immobility.[17] Initially termed *nonanesthetics*, the terminology was revised when it was discovered that at least some of them cause amnesia at similar MAC_{pred} fractions to classic volatile anesthetics.[98] If a molecular or cellular process is affected in similar ways by an anesthetic and a nonimmobilizer, that process is not relevant for the anesthetic state, with the notable exception of amnesia. Despite this elegant rationale, only a limited number of receptors have been excluded because, compared with volatile anesthetics, nonimmobilizers are relatively target selective. These compounds have the potential to provide insights beyond the initially envisaged receptor-level studies by allowing the separation of sedation from amnesia for the study of underlying network activity in vivo.[95]

Photoreactive Anesthetics

An approach that has proven to be very successful with intravenous drugs[270] is one in which an analog of an anesthetic is synthesized that bears a photoreactive group (often a tri-fluoro-diazirine) which, when irradiated at a wavelength of around 300 nm, reacts irreversibly with some amino acids in the anesthetic binding site. This approach, of course, requires that the pharmacologic profile of the analog is very similar to that of the parent compound, so that the relevant binding site is identified. Photoreactive analogs of inhaled anesthetics have been synthesized and four putative sites on $GABA_A$ receptors have been identified.[271]. One advantage of this approach over x-ray crystallography is that anesthetic binding to different conformational states of the receptor are, at least in principle, more accessible to analysis.

GENETIC APPROACHES

Whole-Organism Genetics

Genetic strategies on whole organisms take two forms: forward and reverse.[272] The reverse genetic approach focuses on a particular gene chosen because there are reasons to hypothesize that its product may be important to anesthesia. Examples of this strategy are targeted mutations that alter the sensitivity of specific neurotransmitter receptors to anesthetics.[121] Initially, these mutations were used to identify anesthetic binding sites. Subsequently, transgenic animals rendered resistant to anesthetics, either by deletion of a putative target protein from the genome or by expressing a target receptor engineered to be insensitive to an anesthetic, were used to test behavioral relevance of the altered gene product for the production of anesthesia. Forward genetics, by contrast, is a discovery process that involves the study of randomly generated mutations (either experimentally induced or naturally occurring polymorphisms) that affect the phenotype of interest (i.e., anesthetic end points) in a population. This approach, however, has not been widely used.

Molecular Genetics

A third genetic approach that is playing an increasing role in neuroscience is the selective modification of neuronal function using molecular genetics. Many different approaches are used, ranging from the selective knockdown of specific receptor populations using microRNA (a small noncoding piece of RNA that can selectively reduce protein expression), the block of neurotransmitter release from a population of neurons using tetanus toxin light chain, and the selective activation or inhibition of neuronal networks using optogenetics[273] or pharmacogenetics.[274] A powerful complement to these techniques is the ability to deliver artificial transgenes to defined neuronal populations using adeno-associated virus (AAV), and mouse lines that express Cre recombinase in particular cell types, which allow the selective expression of those genes in those specific cells. These approaches are only just beginning to be used to identify neuronal pathways that are involved in anesthetic action. For example, it has recently been shown that the sedative effects of propofol require the activation of the lateral habenula, an excitatory nucleus that lies close to the thalamus.[275] These approaches are likely to have an increasing impact on our understanding of the mechanisms of inhaled general anesthetics.

Knockout and Knockin Animals

In the knockout approach, expression of the gene encoding a protein of interest is disrupted by a specific deletion or insertion. Nearly all such studies have been carried out in mice. A well-recognized problem with the global knockout approach is that extensive compensatory changes can be induced, from anomalies that are lethal in utero to insidious (but experimentally confounding) influences that might be expressed only at maturity. A complementary strategy is the conditional knockout, in which the genetic deletion is restricted either anatomically (limited to certain brain regions) or temporally (at a known point in time). These strategies can minimize developmental anomalies and reduce the likelihood of compensatory changes. In the knockin approach, a mutation, usually of a single amino acid residue, is targeted to produce a protein with altered sensitivity to a drug of interest. Ideally, this mutation remains completely silent in the absence of the drug; that is, it does not perturb the normal expression and function of the protein of interest or alter the expression of other genes.

$GABA_A$ receptors. Results from transgenic animals illustrate both the utility and the difficulties of the genetic approach with respect to inhaled agents. The conditional forebrain-restricted $GABA_A$ receptor α_1-subunit knockout mouse was found to be less sensitive to isoflurane-induced amnesia than wild-type mice, which led to the conclusion that action at these receptors contributes to isoflurane's amnesic effects.[276] By contrast, a mouse harboring a mutation of the $GABA_A$ receptor α_1 subunit that renders the receptor insensitive to isoflurane in vitro did not show reduced sensitivity to either the amnesic or the immobilizing effects of isoflurane, leading to the conclusion that this subunit does not mediate the impairment of learning and memory by isoflurane.[40] Similar experiments indicate that action at the $GABA_A$ receptor β_3 subunit does not mediate immobility or amnesia by isoflurane.[39] This bottom-up genetic approach is a work-intensive but powerful tool that has yielded clear results with the receptor-specific intravenous anesthetics,[27] but it has proved challenging to apply it to the more promiscuous inhaled agents.

Glycine α1–containing receptors. Pharmacologic studies supported the notion that glycinergic neurotransmission might be the effector for the immobilizing action of inhaled anesthetics in the spinal cord, where glycine replaces GABA as the principal inhibitory transmitter. However, mice harboring mutations that render α_1 subunit–containing glycine receptors largely insensitive to alcohol and inhaled ether anesthetics did not demonstrate a concordant change in MAC values. Because α_1 is the most widely expressed subunit in adult animals, it is unlikely that action at glycine receptors plays an important part in the immobilizing action of inhaled anesthetics.[276]

Two-pore domain K^+ channels. Use of mice harboring knockout mutations of several two-pore domain K^+ channel (K_{2P}) family members (TASK-1, TASK-3, TREK-1) has demonstrated a role for these channels in volatile anesthesia.[44,45,47] For example, TREK-1 knockout mice are partially resistant to all volatile anesthetics tested with respect to both loss of righting reflex (a surrogate measure of consciousness) and immobility, but anesthesia can still be induced, albeit at higher anesthetic concentrations. Interestingly, responses to pentobarbital are unaffected, indicating that the mutation does not cause a generalized resistance to anesthesia.

FORWARD AND POPULATION GENETICS

The nematode *C. elegans* and the fruit fly *Drosophila melanogaster*, with 302 and 100,000 neurons, respectively, have also been used as model organisms in anesthesia research.[277] Mutations in a number of *C. elegans* genes affect sensitivity to volatile anesthetics,[278] most notably *unc-1*,[279] a close homologue of the mammalian protein stomatin.[280] Yeasts have also been used as model organisms, with even more obvious limitations with respect to identification of appropriate anesthetic end points.

Sensitivity to anesthetics is a quantitative trait (varying continuously in a population). Quantitative genetics is the study of the heritability of continuous traits. These traits are controlled by genes represented in quantitative trait loci (QTLs). A top-down population-based approach has been used to localize QTLs that govern susceptibility of individuals to anesthetics, in higher and lower organisms. Starting from the observation that inbred mouse strains vary in their sensitivity to isoflurane, microsatellite-based linkage analysis and, alternatively, single-nucleotide polymorphism–based analysis of genetic variation localized a QTL for isoflurane immobilization to the proximal part of mouse chromosome 7.[281] Genetic variability in the sensitivity of *D. melanogaster* to inhaled anesthetics has also been demonstrated.[282] This type of analysis promises to assist in defining the genetic basis for variability in the susceptibility to both primary anesthetic end points and side effects.

FUNCTIONAL IMAGING AND HIGH-DENSITY ELECTROENCEPHALOGRAPHY

Identification of the anatomic and functional substrates for anesthetic effects on consciousness, memory, and immobility is now approachable with improved imaging techniques. Imaging is based on mapping of either metabolic or hemodynamic changes as surrogate measures of neuronal activity, as in positron emission tomography (PET) and functional magnetic resonance imaging, or on mapping electrical activity with high-density EEG, magnetoencephalography, and low-resolution brain electromagnetic tomography. Properties of receptors can also be probed with radioactive ligands by PET. These techniques have the capacity to identify neuroanatomic substrates of drug action with method-specific limitations. Results from functional PET imaging suggest that propofol suppresses episodic memory by targeting the prefrontal and posterior parietal cortex as opposed to the medial temporal lobe[283] and that suppression of consciousness is caused by anesthetic action in the thalamus, parts of the medial and posterior parietal cortex, and/or the posterior cingulate and medial parietal cortex.[284] Although observations of regionally specific and global suppressive effects of anesthetics on metabolic activity are unlikely to provide a definitive mechanistic understanding, such information can facilitate hypotheses and experimentally testable predictions.

Advanced analytical approaches based on theories from mathematical and statistical sciences are being increasingly applied to enhance the power of existing technologies. Magnetic resonance images and high-density EEG recordings of the brain reveal strong interregional connections, but the considerable potential of this connectivity information to better understand the brain's response to anesthesia has only recently begun to be tapped. The growing use of invasive recording techniques (e.g., brain surface electrode grids and microelectrodes implanted deep into the brain for functional neurosurgical therapies) is also advancing the frontiers of neuroscience in general and the understanding of anesthetic mechanisms in particular.

Summary

The mechanisms of inhaled anesthetics have proved more difficult to explain than was envisaged a generation ago, when the paradigm shifted from lipids to amphiphilic cavities in proteins as targets for anesthetics. Despite a remarkable accumulation of information, a comprehensive theory of general anesthetic action has yet to be formulated. Progress toward this goal has been difficult for several reasons. Important pharmacologic characteristics of inhaled anesthetics that have impeded identification of their relevant molecular targets are their low potency (micromolar range), activity at multiple targets, lack of specific antagonists, and limitations in the neuroscience of memory and consciousness. This contrasts with the situation for intravenous anesthetics, which exhibit more conventional receptor pharmacology. Moreover, accumulating evidence indicates that no universal target exists to explain the actions of every general anesthetic or even of a single anesthetic agent. It is now clear that the composite state of anesthesia and its core components (amnesia, sedation/unconsciousness, immobility) are separable behavioral states in vivo. Resolution of these phenomena at the molecular and cellular levels represents the cutting edge of contemporary neuroscience. Of the multiple molecular and cellular anesthetic effects identified, it is unclear which are critical for the desired behavioral end points, which are harmless or beneficial side effects (e.g., preconditioning), and which, if any, could have long-lasting or delayed undesirable consequences (e.g., cell death, cognitive dysfunction). Progress in identifying the molecular targets of general anesthetics provides a foundation for identification of the network- and systems-level effects relevant to their behavioral and peripheral end points. As the biologic foundations of behaviors once thought to be exclusively the realm of psychology are unraveled, for which anesthetics provide a valuable investigative tool, a comprehensive theory of anesthesia will also develop.

Inhaled Anesthetic Uptake, Distribution, Metabolism, and Toxicity

STUART A. FORMAN and YUMIKO ISHIZAWA

KEY POINTS

- The alveolar anesthetic concentration (F_A) or partial pressure (P_{alv}) is important because it is the driving force determining anesthetic uptake into blood and target tissues in the central nervous system, and it can be monitored as a readout of anesthetic dosage. P_{alv} is influenced by both delivery and uptake of anesthetic gas.
- Inhaled anesthetic delivery to patients can be increased with larger fresh carrier gas flows, vaporizer output settings, and minute ventilation.
- Initial anesthetic uptake into blood increases with greater pulmonary blood flow (cardiac output) and high blood solubility of anesthetic gas. Increased uptake (as with a highly blood-soluble drug or high cardiac output) slows anesthetic induction because it slows the rate of rise of P_{alv}. Conversely, low anesthetic solubility in blood is associated with rapid onset and offset of anesthesia.
- Uptake of anesthetic into blood slows as blood and tissue partial pressures increase, resulting in higher anesthetic partial pressure in mixed venous blood.
- The higher the inspired anesthetic concentration, the less it diminishes because of uptake (the concentration effect). At 100% inspired concentration of a gas, uptake reduces the volume of gas in alveoli, but does reduce P_{alv}. During inhalation of anesthetic mixtures containing high nitrous oxide (N_2O) concentrations, the reduction of alveolar volume produced by rapid N_2O uptake sustains or increases the concentrations of other alveolar gases (the second gas effect).
- Factors that affect anesthetic uptake similarly affect pulmonary clearance of anesthetics. The rate of clearance is also context sensitive—that is, equivalent drops in alveolar and brain anesthetic concentrations are slower after a long exposure to inhaled anesthetic compared to a short exposure of equal depth.
- Toxicities of inhaled anesthetics that last beyond the exposure period are primarily associated with their biotransformation (metabolism). These toxic effects are usually produced in the tissues, such as liver and kidney, in which metabolism occurs. Modern inhaled anesthetics undergo less metabolism than older drugs, resulting in less hepatic and renal toxicity.
- Halothane hepatitis is a potentially fatal syndrome of fulminant liver damage after exposure to reactive metabolites produced by oxidation of volatile anesthetics. These metabolites covalently modify liver proteins, creating neohaptens that elicit an immune response against hepatocytes. The incidence of the syndrome varies with different anesthetics, paralleling the extent of drug metabolism: halothane >> enflurane > isoflurane > desflurane.
- Defluorination of inhaled anesthetics occurs in both the liver and kidney, producing high fluoride concentrations in blood. Renal toxicity characterized by high-output renal failure is almost exclusively associated with prolonged exposure to methoxyflurane. Sevoflurane metabolism also results in high fluoride levels in blood but does not damage kidneys. Factors that enhance the toxicity of methoxyflurane relative to sevoflurane include its higher tissue solubility, slower clearance, and higher degree of renal metabolism, resulting in high intrarenal fluoride levels for an extended time.
- In laboratory mammals, including nonhuman primates, all general anesthetics alter synapse and neural circuit formation during critical periods of brain development, resulting in abnormal memory and behavior. Clinical studies in children suggest that lengthy (>4 hours) anesthetic exposures at under 2 years of age are associated with detectable but quite small neurocognitive deficits, relative to unexposed controls (also see Chapter 77. Postoperative delirium and cognitive decline/dysfunction (POCD) in elderly patients is also a growing concern (see Chapter 83). Based on animal and clinical studies, both postsurgical neuroinflammation and exposure to general anesthesia may contribute to POCD.
- Anesthetics react with strong bases, particularly potassium hydroxide (KOH), in carbon dioxide (CO_2) absorbents, resulting in production of several potentially toxic substances. Sevoflurane

degrades to form compound A, which is associated with renal damage in rodents, but not in humans. This differential toxicity is associated with differential renal metabolism in rodents versus humans. Dry CO_2 absorbents in the breathing circuit react with inhaled anesthetics, releasing carbon monoxide and heat. New CO_2 absorbent materials that lack strong base chemicals prevent these reactions and subsequent potential harm to patients.

- N_2O is unique among anesthetics in its ability to inhibit methionine synthase by oxidizing a cofactor, vitamin B_{12}. In certain susceptible patients or with multiple frequent exposures to N_2O, methionine synthase inhibition can lead to hematologic and neurologic dysfunction. After prolonged N_2O exposure, methionine synthase inhibition also increases blood homocysteine, which is hypothesized to increase vascular inflammation and the risk of thrombosis. Large clinical trials show that N_2O exposure does not increase the risk of cardiovascular morbidity in most patients, but N_2O should be avoided in patients with deficiencies in dietary B_{12} intake or absorption or B_{12}-dependent metabolism.
- Inhaled anesthetics, when scavenged and ejected into the atmosphere, contribute to both global warming and ozone depletion. Minimizing the environmental impact of inhaled anesthetics requires reducing waste, through the routine use of low fresh gas flows and/or by use of new technologies that trap scavenged anesthetic gases. Reprocessing and reusing trapped anesthetic gases further reduce the environmental impact of drug production.

Introduction

Modern inhaled anesthetics are important pharmacologic tools for reversibly altering central nervous system (CNS) functions in patients. Because inhaled anesthetics are both taken up and eliminated through alveolar blood-gas exchange, drug dosage can be monitored in expired alveolar gases and tissue-dependent metabolism is unnecessary for drug clearance. Optimal delivery of systemic drugs via inhalation requires a full understanding of the factors influencing how gas-phase compounds move into and out of various body tissues and how they are metabolized (pharmacokinetics) together with knowledge of where and how these drugs and their metabolism affect tissue functions. Reversible anesthetic effects on the nervous, respiratory, and cardiovascular systems (pharmacodynamics) are covered elsewhere in this book (see Chapters 11, 14, 19, and 21).

Uptake and Distribution of Inhaled Anesthetics

In the first part of this chapter, we review and apply some of the basic principles of chemical equilibria to illuminate major factors influencing inhaled anesthetic uptake and distribution in patients. For this, we use a physiologic model that closely simulates clinical observations. The model, an elaboration of that introduced in 1973 by Mapleson,[1] is described both qualitatively and quantitatively (using mathematical expressions) to convey important concepts to readers with different learning styles.

BIOPHYSICAL PROPERTIES OF INHALED ANESTHETICS: PARTIAL PRESSURE, HYDROPHOBICITY, AND PARTITION COEFFICIENTS

Inhaled anesthetics are administered as a component of a gas mixture. Biophysical properties of inhaled anesthetics are summarized in Table 20.1.[2-11] ***Partial pressure*** is the portion of total pressure contributed by one component of a gas mixture, where each component contributes pressure in direct proportion to its molar fraction. For example, 1.5% isoflurane in air (21% O_2 and 79% N_2) at 1 standard atmosphere (atm) (760 mm Hg) is a mixture of O_2 at 157.2 mm Hg, N_2 at 591.4 mm Hg, and isoflurane at 11.4 mm Hg. The partial pressure of an anesthetic gas is a measure of its thermodynamic activity and determines its pharmacologic effect. The partial pressure of an anesthetic is usually reported as the percentage (or fraction) of the delivered gas mixture, where atmospheric pressure is near 1 atm (760 mm Hg). Correcting these values to absolute partial pressure is important under conditions when local atmospheric pressure differs significantly from standard, such as at high altitude, underwater, or in a hyperbaric chamber. The same inhaled concentration of an anesthetic gas results in a reduced pharmacologic effect at higher altitudes because the partial pressure of the anesthetic is lower. Because partial pressure is the thermodynamic force for gas transfer between compartments in a system, anesthetics move from regions of high partial pressure to low partial pressure, unaffected by the other components of the gas mixture, and equilibrium is achieved when the partial pressure of an anesthetic is equal in the different compartments.

The maximum partial pressure of a volatile compound is its ***vapor pressure***; this is the partial pressure of volatile anesthetic (VA) within the drug reservoir of a vaporizer. Vapor pressure is unique to each anesthetic and increases with increasing temperature. VAs are defined by a vapor pressure less than 1 atm at 20°C and a boiling point above 20°C (see Table 20.1). Gaseous anesthetics are defined by a vapor pressure above 1 atm at 20°C and a boiling point below 20°C (see Table 20.1). VAs typically compose a small fraction of the gas mixture delivered to patients. In contrast, gaseous anesthetics such as nitrous oxide (N_2O) and xenon, because of their relatively low anesthetic potencies, typically compose a large fraction of an inhaled gas mixture, and thus produce additional effects (e.g., concentration effect, second gas effect, and airspace expansion) that are negligible with VAs.

Hydrophobicity is a molecular property of certain chemicals, including most general anesthetics that do not

*MAC is minimal alveolar concentration for subjects approximately age 40 years.
Partition coefficients are from the following references[2-6]:
MAC-immobility and MAC-awake values are from the following references[2,7-11]:
Properties are measured at standard temperature (20°C) and pressure (1 atm) unless otherwise specified.

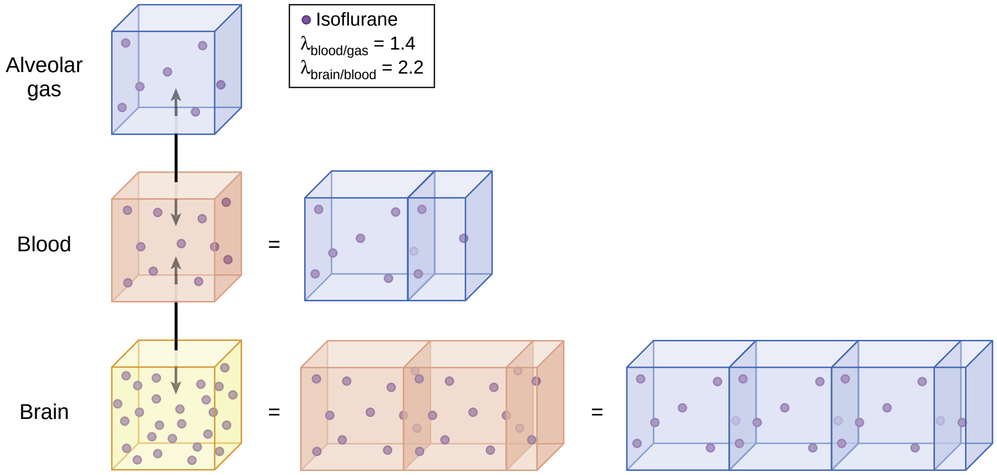

Fig. 20.1 Partitioning of anesthetic gases between different biophases. Left, Depicts the partitioning of isoflurane between gas phase *(blue)*, blood *(red)* and brain *(yellow)*. The blood:gas partition coefficient ($\lambda_{b/g}$) for isoflurane is 1.4 and the brain:blood partition coefficient ($\lambda_{CNS/blood}$) is 2.2 (see Table 20.2). At equilibrium, defined as equal isoflurane partial pressure in all compartments, a volume of blood contains 1.4-fold the quantity of isoflurane as the same volume of alveolar gas, whereas a volume of brain tissue contains 2.2-fold the quantity of isoflurane as the same volume of blood. Right, We also depict partition coefficients as effective (equivalent) volumes of another biophase. For example, 1 volume of blood contains the same amount of isoflurane as 1.4 volumes of alveolar gas, whereas 1 volume of brain contains the same amount of isoflurane as 2.2 volumes of blood or 3.1 volumes of gas.

readily form hydrogen bonds and therefore display low water solubility. Hydrophobic compounds are also usually *lipophilic*, demonstrating high solubility in low polarity solvents such as oils. Common measures of hydrophobicity are ***partition coefficients*** between water and olive oil (which is mostly oleic acid, an 18-carbon fatty acid) or between water and n-octanol. Usually represented by the Greek letter lambda (λ), a partition coefficient is the ratio of two solute concentrations *at* ***equilibrium*** (i.e., at equal partial pressure) in two separate but adjacent solvents or compartments such that the solute moves freely between the compartments (Fig. 20.1). Another useful way to conceptualize a partition coefficient is that it represents the *relative volume of two phases or compartments that contain an equal amount of the solute at equilibrium* (see Fig. 20.1).

Anesthetic partition coefficients between blood and gas ($\lambda_{b/g}$) and between tissue and blood ($\lambda_{t/b}$) are important factors in uptake and distribution of inhaled drugs as they move from pulmonary airspace to pulmonary blood and then from blood to various tissues (Tables 20.1 and 20.2).[6,12-15] The blood solubility of anesthetic gases (and other gases such as O_2, N_2, and CO_2) increases as temperature decreases.[16,17] Because most anesthetics are hydrophobic, they tend to display high solubility in tissues with high lipid content (e.g., fat), and also bind to many proteins that form hydrophobic or amphiphilic pockets.[13] Anesthetic partitioning into blood (blood solubility) increases after ingestion of fatty foods[18] and may decrease in anemic or malnourished patients. Methoxyflurane (no longer in clinical use) and halothane are notable for high blood solubility. N_2O, sevoflurane, and desflurane are characterized by low blood solubility.

ANESTHETIC DELIVERY, UPTAKE, AND DISTRIBUTION: A MULTICOMPARTMENTAL MODEL

Delivering an inhaled anesthetic agent to patients is analogous to an intravenous drug infusion with two major differences: (1) entry of drug into the body is via transalveolar exchange from gas to blood, and (2) clearance is mostly via the same route. Thus inhaled anesthetic delivery is dependent on pulmonary ventilation, whereas uptake and clearance of inhaled anesthetics are also dependent on pulmonary perfusion.

Upstream and Downstream Compartments and Anesthetic Transfer: Bulk Flow and Pressure Gradients

Uptake and distribution of inhaled anesthetic can be readily understood as a series of transfer steps from upstream compartments with high partial pressure to downstream compartments with low partial pressure as depicted in Fig. 20.2. First, drug is transferred from an anesthesia delivery device, typically an anesthesia machine with a vaporizer designed to deliver specified concentrations (in percent atm) of VA agent, into a fresh gas mixture flowing in a breathing circuit. Second, ventilation transfers gases from the circuit to the alveolar airspace in lung. Third, anesthetic moves by transcapillary diffusion into pulmonary venous blood. Fourth, arterial blood distributes anesthetic to various tissues including the primary target tissue, the CNS. Fifth, venous outflow from tissues converges in the pulmonary artery, and sixth, the mixed venous blood passes through alveolar capillaries where it again equilibrates with alveolar gases.

Gas flow from the anesthesia machine into the breathing circuit is unidirectional. Blood circulation is also largely unidirectional. In transfers from the anesthesia machine (the fresh gas outlet) to breathing circuit and then to alveolar airspace, anesthetic flow can simply be understood as exchange from upstream compartments into downstream compartments. In later steps, such as exchange between alveolar gases and pulmonary capillary blood, flow of anesthetic molecules occurs via diffusion between adjacent compartments separated by a permeable membrane. For simplicity, we have not treated blood as a separate compartment in our model. Distribution of anesthetic to and from various tissues involves both bulk transfer via blood flow

Based on a 70 kg pt at rest. Blood and tissue partition coefficients are from references 6 and 12-14. Tissue volumes and blood flow values are approximate (Kennedy et al.[15] and Levitt[13]). Effective volumes are calculated as tissue volume × $\lambda_{\text{tissue/blood}}$ and exchange time constant (τ) for each compartment is V_{eff}/blood flow.

[*] Blood/gas partition coefficients for anesthetic agents are given in Table 20.1.

CNS, Central nervous system; *VPT*, vessel-poor tissues (e.g., skin, bone, and connective tissues).

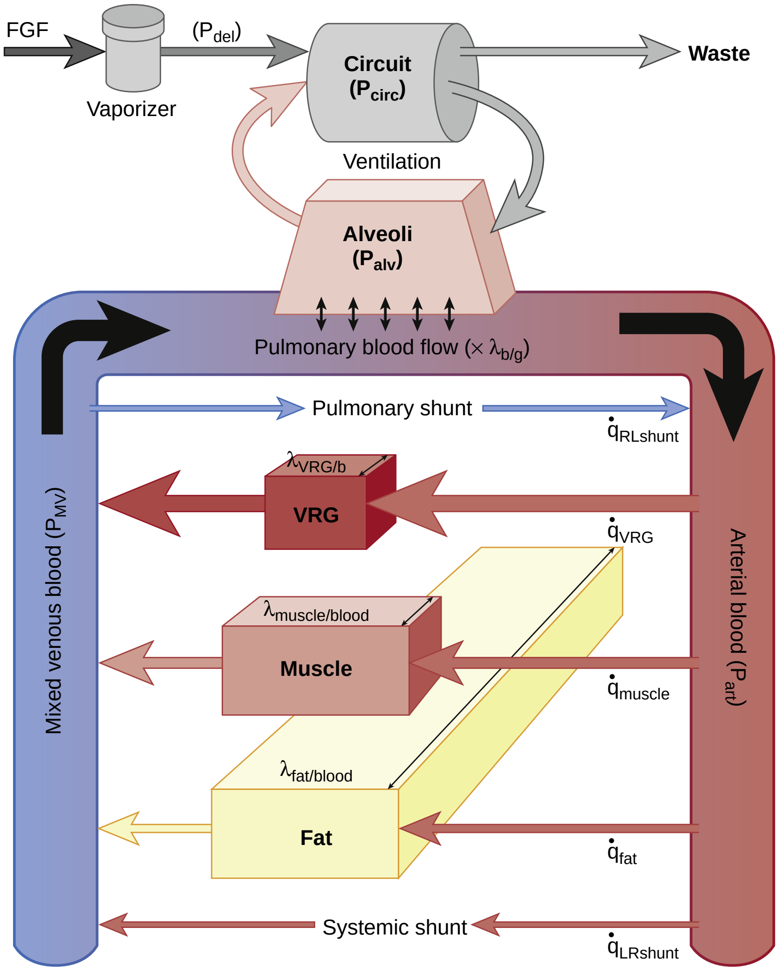

Fig. 20.2 Flow diagram for uptake and distribution of inhaled anesthetics. Major compartments for anesthetic flow are depicted, including the breathing circuit, alveolar gas space, and three major tissue compartments: vessel-rich group (VRG), muscle, and fat. The physiological volumes of the tissue compartments are approximately in proportion to the labeled face of the compartment, while the blood-tissue partition coefficients are depicted as the depth of the compartment. Thus the effective volume of the VRG is much smaller than that of muscle, which in turn is much smaller than that of fat. Carrier flows and exchange in different parts of the model are depicted by arrows: Fresh gas flow *(FGF)* moves anesthetic from the vaporizer to the circuit; ventilation drives exchange of anesthetic between the circuit and alveoli; pulmonary blood flow transfers anesthetic from alveoli into the circulation, which then distributes drug to different compartments depending on blood flow to various tissues. Relative blood flow is approximately proportional to the width of the arrows into and out of tissue compartments, as well as for shunts. The diagram depicts an early phase of anesthetic uptake when organs of the VRG, including the brain, are approaching equilibrium with alveolar and arterial anesthetic partial pressure, while anesthetic partial pressures in muscle and fat remain relatively low. Quantitative modeling of anesthetic gas movement in this system was performed using numerical integration of equations describing anesthetic flow into and out of each compartment (Eqs. 20.5, 20.8–20.11). Figs. 20.4–20.7, 26.9, 20.10, and 20.12 were all generated using this model. Standardized parameters used in the model are summarized in Table 20.2.

and diffusive equilibration across capillary membranes. Note that when anesthetic transfer occurs between gas and blood or between blood and tissue, the effective volume of the downstream compartment must be adjusted with the appropriate partition coefficient (see Table 20.2).

Rate of Wash-In of the Circuit: Equilibration Between Vaporizer and Circuit

Equipment for controlled delivery of inhaled anesthetic drugs are described elsewhere in this text (see Chapter 22). Wash-in of the ventilator breathing circuit represents an example of bulk transfer exchange, wherein the gas in circuit components is replaced by fresh gases emerging from the gas outlet of the anesthesia machine.

Anesthetic Delivery from the Vaporizer: VA delivery (in liters per minute of gaseous drug) from a vaporizer is closely approximated as the product of the delivered anesthetic concentration (fraction = F_{del} or partial pressure at 1 atm = P_{del}) of the anesthetic in a gas mixture and the fresh gas flow (FGF):

$$dVA_{del}/dt = P_{del} \times FGF. \tag{20.1}$$

Thus we can readily calculate the volume of delivered gas-phase anesthetic by simply integrating this function over time. In the simplest case where P_{del} and FGF remain constant,

$$VA_{del}(t) = P_{del} \times FGF \times t. \tag{20.2}$$

Fresh Gas Wash-In to the Breathing Circuit: The factors that affect the speed at which the gas mixture delivered from the anesthesia machine replaces gases in the breathing circuit (wash-in) are FGF and the breathing circuit volume (V_{circ}). Consider a typical situation where FGF at the beginning of an anesthetic is 6 L/min, and the gas volume inside the components of a breathing circuit is 6 L. If FGF is doubled to 12 L/min, then wash-in will proceed at twice the rate (halving the time). Conversely, if the V_{circ} doubles to 12 L, then wash-in will proceed at half the rate (doubling the time).

The gas exchange process is independent of the concentration of anesthetic in the circuit, because the exchange is simply through bulk flow and mixing. However, the *difference between the delivered concentration and that in the circuit determines the magnitude and direction of net anesthetic gas flow*. When the delivered anesthetic partial pressure (P_{del}) is greater than that in the circuit (P_{circ}), net anesthetic flow is into the circuit (and subsequently the patient). To remove anesthetic from the circuit, P_{del} must be less than P_{circ}. When there is no concentration gradient (i.e., equal partial pressures), bulk flow exchange may replace all the old anesthetic molecules with new ones, but there is no net flow and anesthetic concentrations in the circuit remain unchanged.

Mathematically, we can describe the breathing circuit exchange process as a differential equation that incorporates all of the above factors:

$$\frac{dP_{circ}}{dt} = \frac{FGF}{V_{circ}} \times (P_{del} - P_{circ}). \tag{20.3}$$

If P_{del} is constant, integrating this equation results in a single exponential function that defines P_{circ} at any given time following a change in P_{del} at t = 0:

$$P_{circ}(t) = P_{circ}(0) + (P_{del} - P_{circ}(0)) \times \left(1 - e^{-t/[V_{circ}/FGF]}\right) \tag{20.4}$$

P_{circ} approaches P_{del} following an exponential time course with a time constant of $\tau = V_{circ}/FGF$. Thus if V_{circ} = 6 L and FGF = 6 L/min, the exponential time constant will be 1 minute (Fig. 20.3). Each minute results in the fraction of old gas in the breathing circuit dropping by 63.1%, and after 4 minutes, less than 2% old gas remains. The half-life for the process (time for halving the vaporizer-circuit concentration difference) is $0.693 \times \tau$.

Breathing circuit components, such as CO_2 absorbents and the plastic or rubber of the circuit tubing and connectors, influence the rate of equilibration between vaporizer and circuit, because they absorb VAs, increasing the effective circuit volume.[19] The more hydrophobic VAs absorb more into circuit components, whereas absorption negligibly affects wash-in and wash-out of low-solubility anesthetics.

The clinical relevance of the wash-in process is readily appreciated. An example of the importance of FGF is "priming" the anesthetic circuit for a single-breath induction technique. The FGF setting and the circuit volume influence the required duration of priming. More generally, whenever the vaporizer settings are altered, the speed at which the new settings influence the wash-in or wash-out of the circuit (and subsequently the patient) will depend on FGF. Open (nonrebreathing) anesthetic breathing circuits are designed to have low exchange volumes and to be used with high fresh-gas flows. These features allow rapid changes in the delivered anesthetic concentration, while minimizing rebreathing of exhaled gases. The choice of an open versus rebreathing system influences the impact of various other factors that can affect uptake and distribution of inhaled anesthetics downstream from the breathing circuit. Some of the subsequent figures show models for both conditions.

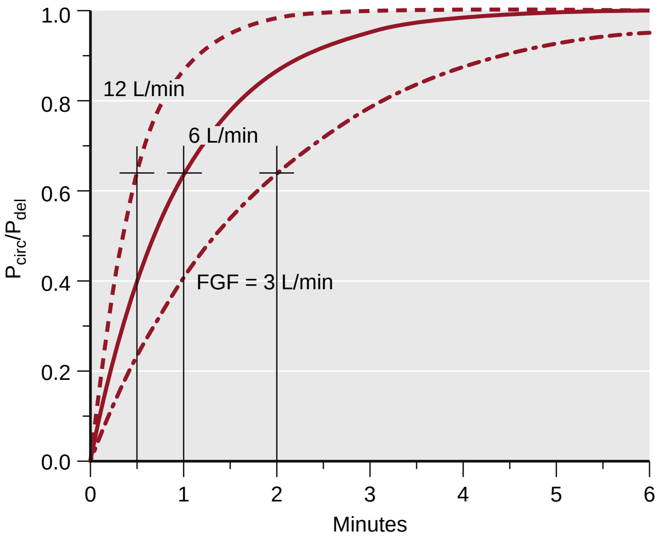

Fig. 20.3 Wash-in of the breathing circuit depends on fresh gas flow (FGF). The curves depict the rate of rise of anesthetic concentration (partial pressure) in a breathing circuit with 6 L gas volume, depending on FGF. Higher FGF results in more rapid exchange of circuit gases with fresh gas. The exponential time constant for the wash-in process is the circuit volume in liters divided by FGF flow in liters per minute (see Eq. 20.4). Cross marks overlaying the curves indicate time constants under different gas flow rates. Each time constant correlates with a 63.1% exchange.

Equilibration Between Circuit and Pulmonary Airspace

Transfer of anesthetic gases from the breathing circuit to the pulmonary airspace is another bulk exchange process similar to that from vaporizer to breathing circuit. In this case, gas flow via ventilation is cyclical and bidirectional, and the factors that determine the rate of anesthetic exchange are minute ventilation (MV) and total pulmonary airspace volume (V_{pulm}).[20] Because transfer from the circuit to the lungs represents anesthetic flow out of the circuit, we alter Eq. (20.3) to include both inflow to the circuit and outflow from the circuit,

$$\frac{dP_{circ}}{dt} = \frac{FGF}{V_{circ}} \times (P_{del} - P_{circ}) - \frac{MV}{V_{pulm}} \times (P_{circ} - P_{pulm}), \tag{20.5}$$

where P_{pulm} is a weighted average of the anesthetic partial pressure in dead space and alveolar space.

Eq. (20.5) describes how rebreathing affects the inhaled (breathing circuit) anesthetic concentration. Most inhaled anesthetics are delivered using a rebreathing circuit, which includes one-way flow valves and adsorbent material to chemically remove exhaled CO_2. Rebreathing depends primarily on the balance between fresh gas flow and MV. The anesthetic gas in the breathing circuit represents a mixture of fresh gas and exhaled gases. Increased fresh gas flow reduces rebreathing, whereas increased MV increases rebreathing.

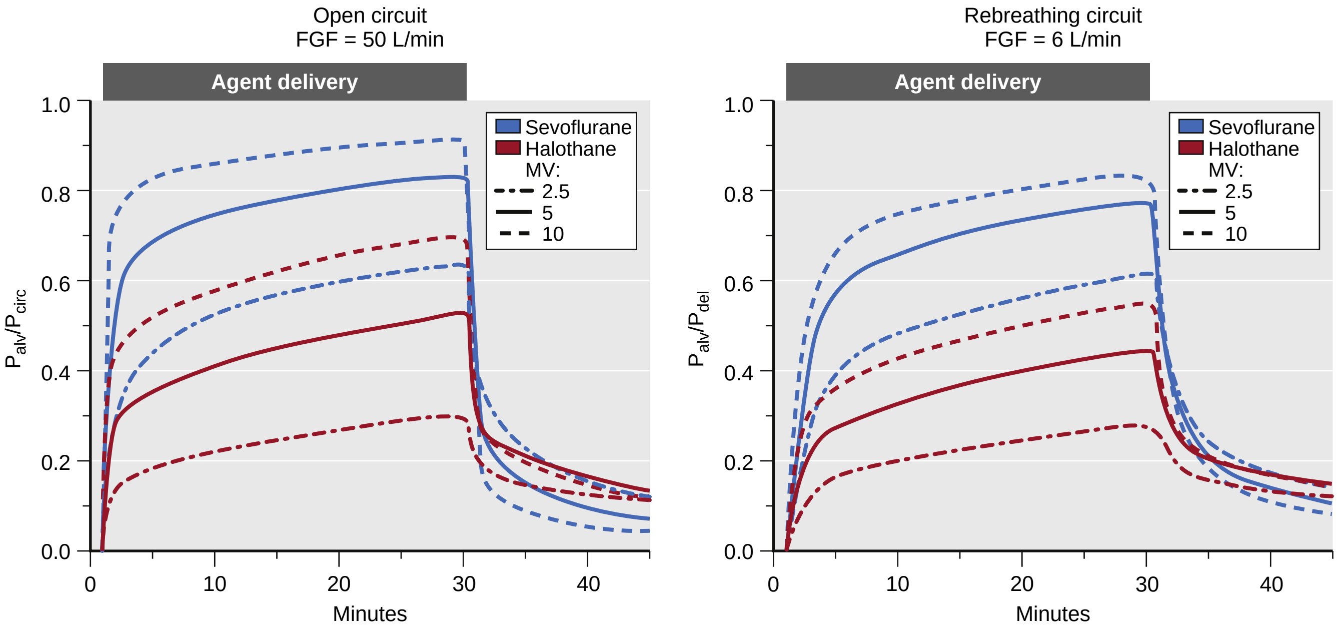

Fig. 20.4 Effect of ventilation on the rise of alveolar anesthetic partial pressure (P_{alv}). Left, A traditional open-circuit model with very high fresh gas flow *(FGF)* and therefore constant $P_{del} = P_{circ}$. Right, A more common clinical situation with constant vaporizer output (P_{del}) and partial rebreathing at a 6 L/min fresh gas flow rate. Raising minute ventilation accelerates the rise of P_{alv} by delivering more anesthetic to the lungs. The effect is seen whether anesthetic is highly soluble in blood (e.g., halothane) or relatively insoluble (e.g., sevoflurane). However, the relative size of the ventilation effect is greater for soluble agents. Increased ventilation also accelerates clearance of anesthetic agents after delivery ceases. *MV*, Minute ventilation; *P_{circ}*, Anesthetic partial pressure in the breathing circuit; *P_{del}*, delivered anesthetic partial pressure from the anesthesia machine gas outlet.

The Alveolar Anesthetic Concentration

The alveolar anesthetic concentration (P_{alv} or F_A) is a critically important factor in anesthetic uptake and distribution because (1) it is in rapid equilibrium with circulating blood and highly perfused tissues, including target tissues in the CNS, and (2) P_{alv} can be measured in exhaled end-tidal gases. Thus, except during periods of rapid change, P_{alv} in exhaled breath represents a useful estimate of the anesthetic concentration in the patient's CNS and other highly perfused organs.

Because only alveolar gas is relevant to transpulmonary exchange of anesthetic into and out of the body, *alveolar ventilation* ($\dot{V}_{alv}$) is the proper gas flow to calculate anesthetic exchange into this part of the pulmonary airspace,

$$\frac{dP_{alv}}{dt} = \frac{\dot{V}_{alv}}{V_{alv}} \times (P_{circ} - P_{alv}), \qquad (20.6)$$

where $\dot{V}_{alv}$ is MV corrected for dead space ventilation.

Alveolar Uptake of Anesthetic into Pulmonary Blood

During inhaled anesthetic induction, anesthetic flows from alveolar gas to pulmonary blood across the alveolar/capillary interface separating these compartments and is driven by the partial pressure gradient between alveolar gas (P_{alv}) and mixed venous blood (P_{MV}) entering the pulmonary arteries. The net flow of anesthetic reverses during anesthetic wash-out when P_{alv} drops below P_{MV}. Anesthetic uptake into blood also depends on the pulmonary blood flow (which is typically close to cardiac output, $\dot{Q}$) and the blood's capacity to solvate anesthetic from the gas state (the blood/gas partition coefficient, $\lambda_{b/g}$):

$$\text{uptake} = \dot{Q} \times \lambda_{b/g} \times (P_{alv} - P_{MV}). \qquad (20.7)$$

We therefore correct Eq. (20.6) to reflect both anesthetic inflow into alveolar airspace and its uptake into blood:

$$\frac{dP_{alv}}{dt} = \frac{\dot{V}_{alv}}{V_{alv}} \times (P_{circ} - P_{alv}) - \frac{\dot{Q} \times \lambda_{b/g}}{V_{alv}} \times (P_{alv} - P_{MV}). \qquad (20.8)$$

Thus, during an inhaled anesthetic induction, the rate of increase of P_{alv} relative to P_{circ} is governed by (1) alveolar ventilation, (2) cardiac output, and (3) anesthetic solubility in blood. Increased ventilation delivers more anesthetic from circuit to alveoli and increases P_{alv}/P_{circ} (Fig. 20.4). Importantly, increased pulmonary blood flow removes more anesthetic from alveoli, thereby decreasing the rate of increase in alveolar concentration of anesthetic (P_{alv}/P_{circ}) (Fig. 20.5). Indeed, significant decreases in cardiac output are suspected when end-tidal CO_2 ($ETCO_2$) decreases and end-tidal concentration of VA increases.[21] The more soluble an anesthetic is in blood (i.e., the higher its $\lambda_{b/g}$), the greater is the capacity for each volume of blood to take up anesthetic from alveolar gases (i.e., the larger the effective blood flow). Thus as $\lambda_{b/g}$ increases, P_{alv}/P_{circ} increases more slowly (Fig. 20.6).

Other Factors That Affect the Rate of Rise of P_{alv}

Other factors affecting alveolar uptake of anesthetic include ventilation-perfusion matching and the absolute concentration of anesthetic in alveolar gases.

Pulmonary Dead Space. Dead space (ventilated but not perfused pulmonary regions) reduces effective alveolar ventilation (see Eqs. 20.7 and 20.8), and thus slows anesthetic

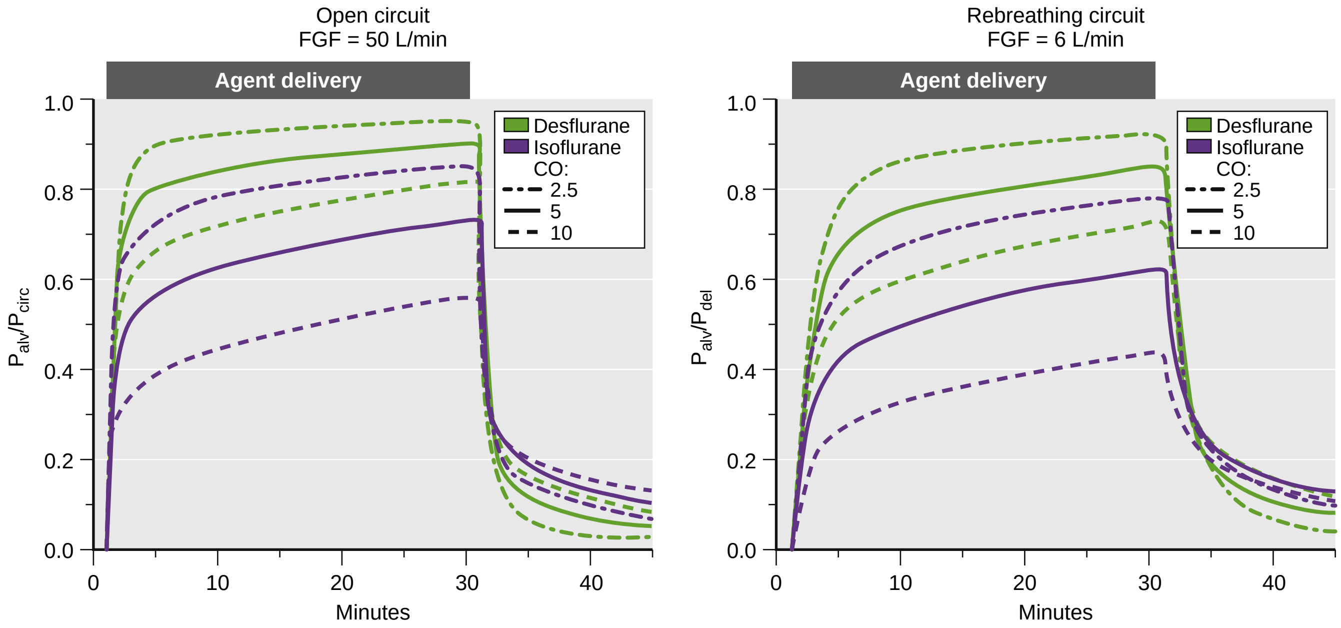

Fig. 20.5 Effect of cardiac output on the rise of alveolar anesthetic partial pressure (P_{alv}). Left, A traditional open-circuit model with very high fresh gas flows and therefore constant $P_{del} = P_{circ}$. Right, A more common clinical situation with constant vaporizer output (P_{del}) and partial rebreathing at a 6 L/min FGF. Increasing cardiac output slows the rise of P_{alv} by increasing anesthetic uptake into blood (removing anesthetic from alveolar gases). This effect is observed for both soluble (e.g., isoflurane) and relatively insoluble (e.g., desflurane) anesthetics, but the relative effect is greater for soluble agents. Cardiac output also affects clearance of anesthetics from the lungs in the same way it affects uptake (i.e., increased cardiac output slows anesthetic clearance rate). *CO*, Cardiac output; P_{circ}, anesthetic partial pressure in the breathing circuit; P_{del}, delivered anesthetic partial pressure from the anesthesia machine gas outlet.

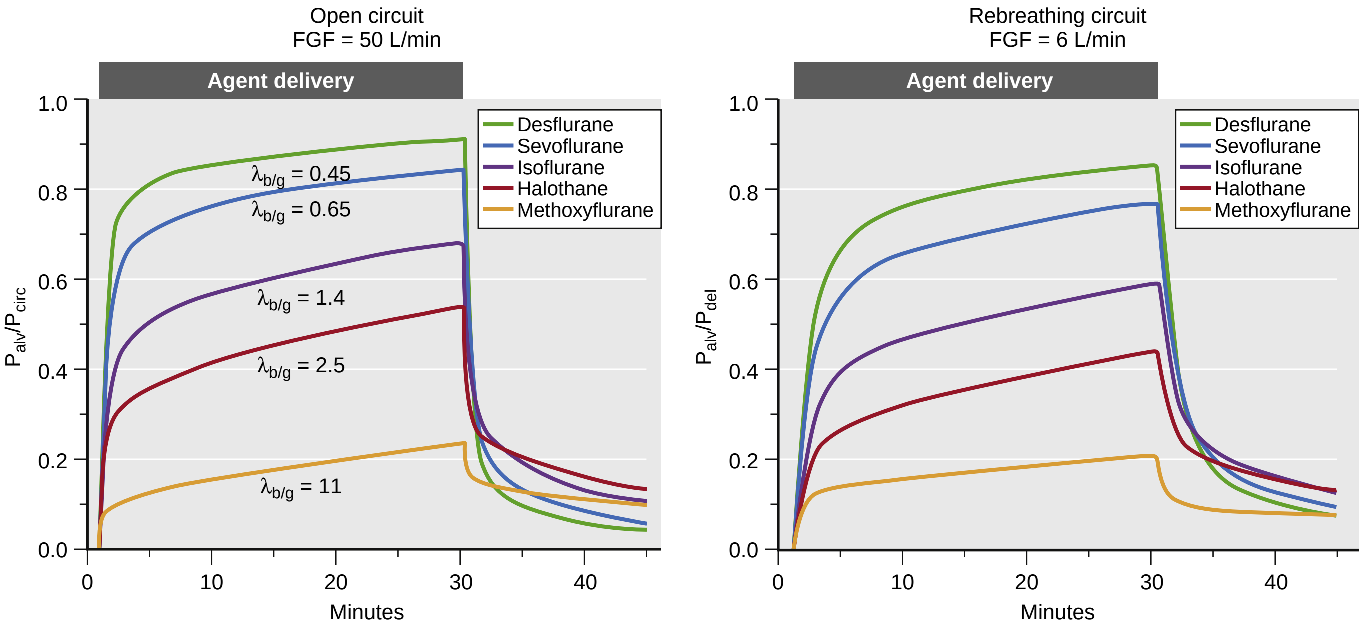

Fig. 20.6 Effect of blood solubility on the rise of alveolar anesthetic partial pressure (P_{alv}). Left, A traditional open-circuit model with very high fresh gas flow (FGF) and therefore constant $P_{del} = P_{circ}$. Right, A more common clinical situation with constant vaporizer output (P_{del}) and partial rebreathing at a 6 L/min FGF rate. As blood solubility ($\lambda_{b/g}$) increases, the rate of rise in P_{alv} slows, because uptake into blood is greater for high solubility agents. The major impact of blood solubility is the magnitude of the rapid initial rise in P_{alv}, which represents a balance between anesthetic delivery and uptake into pulmonary blood. Blood solubility similarly affects clearance from alveoli after anesthetic delivery ceases (i.e., increased blood solubility results in slower clearance from alveolar gas). P_{circ}, Anesthetic partial pressure in the breathing circuit; P_{del}, delivered anesthetic partial pressure from the anesthesia machine gas outlet.

uptake. This effect is strongest under conditions of high FGF and low blood-solubility agents, where alveolar ventilation is the limiting factor in uptake. Under conditions of low FGF and a highly blood-soluble agent, increased dead space, by reducing initial uptake, serves to maintain the inhaled anesthetic concentration (P_{circ}), which creates a compensatory increase in P_{alv} and subsequent uptake.

Pulmonary (Right to Left) Shunting. Pulmonary right to left shunting can be physiologic, pathologic, or iatrogenic, such as during one-lung ventilation. Right-to-left shunting results in a difference between P_{alv} and the partial pressure of anesthetic in arterial blood (P_{art}). This is because arterial blood represents a mixture of shunted mixed venous blood combined with blood that has equilibrated with alveolar gases (Eq. 20.9). Because such shunts also reduce transcapillary gas exchange in the lung and slow anesthetic uptake (Eqs. 20.7 and 20.8, after correcting pulmonary blood flow for shunt), right-to-left shunting sustains P_{circ}, an effect that is more pronounced for highly soluble drugs compared with insoluble anesthetics. Thus shunt reduces the ratio of P_{art}:P_{alv} more for insoluble anesthetics, such as N_2O (Fig. 20.7):[22,23]

$$P_{art} = P_{MV} \times \dot{q}_{RLshunt} + P_{alv} \times \left(\dot{Q} - \dot{q}_{RLshunt}\right). \quad (20.9)$$

Concentration and Second Gas Effects. The absolute concentration of anesthetic influences its uptake and that of other gases. In the previous discussion and illustrations, it was presumed that an inhaled anesthetic represents a small fraction of the inhaled gas mixture and that transalveolar uptake of the anesthetic results in a decrease in P_{alv} and negligible changes in alveolar gas volume. However, when the anesthetic represents a large fraction of the inhaled gas mixture, its rapid uptake results in a smaller relative alveolar anesthetic concentration drop, because the volume of alveolar gas also decreases. This is known as the ***concentration effect.***[24] In an imaginary situation where a patient is breathing 100% anesthetic, uptake into pulmonary blood reduces the volume of anesthetic gas in the alveoli without altering its concentration or partial pressure (oxygen-induced atelectasis occurs through a similar mechanism). A typical situation, illustrated in Fig. 20.8, is delivery of 66% N_2O with 33% O_2 and 1% isoflurane. Assuming cardiac output equals 5 L/min, the initial rate of N_2O uptake is given by Eq. (20.7) as 5000 mL/min × 0.47 × 0.66 atm = 1550 mL/min, indicating that a large fraction of N_2O is taken up into blood during the first few breaths. If we assume that half the N_2O and half the isoflurane are rapidly taken up following the first breath of this gas mixture, then alveolar volume drops by 33.5% and the remaining alveolar gas contains 33 parts N_2O, 33 parts O_2, and 0.5 parts isoflurane (49.6% N_2O, 49.6% O_2, and 0.8% isoflurane). Despite 50% uptake of N_2O, the significant reduction in alveolar gas volume results in a concentration of remaining alveolar N_2O that is only 24% less than its initial value.

The ***second gas effect*** is also evident in this example: the rapid uptake of N_2O and reduced alveolar gas volume sustains P_{iso} near its original inspired value and increases alveolar P_{O_2}, thereby augmenting uptake of these gases.[25] The rapid uptake of N_2O into blood also results in an effective increase in MV, because more gas from the breathing circuit is passively drawn into lung as alveolar gas is rapidly absorbed. These effects have been demonstrated in

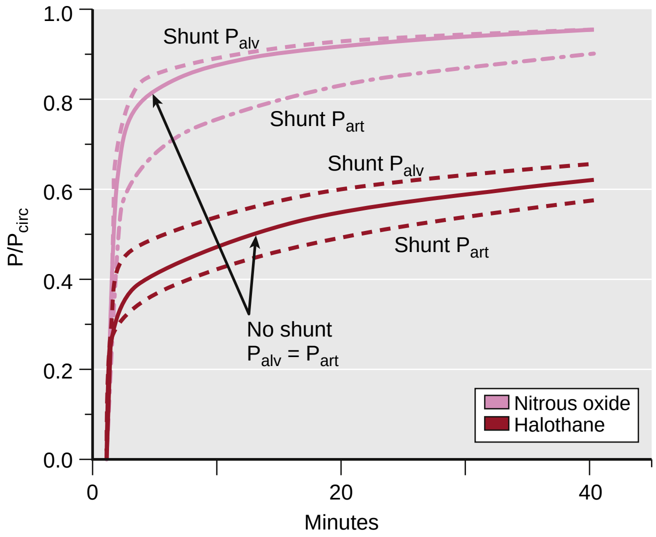

Fig. 20.7 Effect of right-to-left pulmonary shunt on the anesthetic partial pressure in alveolar gas and arterial blood. The curves represent anesthetic partial pressures in alveolar gases *(dashed lines)* and arterial blood *(dash-dot lines)* under conditions of 40% right-to-left shunt and no shunt *(solid lines)*. Pulmonary right-to-left shunting bypasses alveolar uptake, so less anesthetic is removed from pulmonary gases; this accelerates the rise in P_{alv}. In addition, the anesthetic partial pressure in arterial blood (P_{art}) is a mixture of pulmonary venous blood at P_{alv} and shunted mixed venous blood at P_{MV}. Thus P_{art}, which determines the rate of anesthetic uptake into tissues, rises more slowly than P_{alv} when R-to-L shunting is present. The shunt effect on P_{art} versus P_{alv} is larger for insoluble anesthetics (e.g., N_2O) than for soluble anesthetics (e.g., halothane). Other model parameters were set for open circuit delivery (constant P_{circ}) with MV = 6 L/min and CO = 5 L/min. *CO*, Cardiac output; *MV*, minute ventilation; *P_{MV}*, anesthetic partial pressure in mixed venous blood; *P/P_{circ}*.

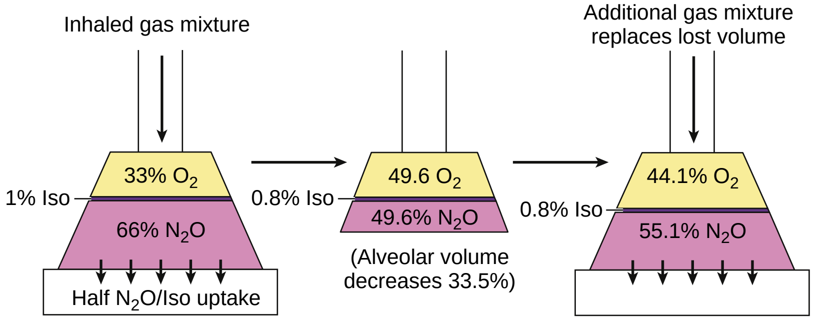

Fig. 20.8 Concentration and second gas effects. The figure depicts alveolar gases at the beginning of an anesthetic. After an initial inspiratory breath, alveoli are filled with the gas mixture in the circuit (66% N_2O, 33% O_2, 1% Isoflurane) at their normal end-inspiratory volume *(left panel)*. After half of the N_2O and isoflurane are absorbed into pulmonary blood, the alveolar gas volume is reduced by 33.5%. At this point, the volume of N_2O equals the volume of O_2 and the gas mixture is 49.6% N_2O, 49.6% O_2, 0.8% isoflurane. Inflow of additional inspired gas mixture returns alveolar volume to its original value, resulting in a gas mixture of 55.1% N_2O, 44.1% O_2, 0.8% isoflurane. The alveolar partial pressure of N_2O falls much less than the fractional uptake (the concentration effect). In addition, the partial pressure of O_2 *increases* relative to the inspired gas O_2 content, and the partial pressure of isoflurane is sustained close to the inspired value, increasing its rate of uptake (the second gas effect). *Iso*, Isoflurane; *N_2O*, nitrous oxide; *O_2*, oxygen.

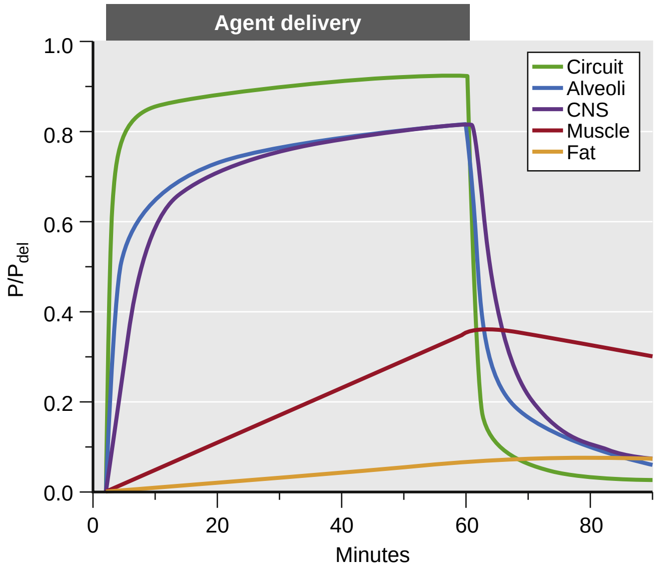

Fig. 20.9 The rate of anesthetic partial pressure rise in different tissue compartments. The curves represent model calculations for sevoflurane delivered at 6 L/min fresh gas flow, with 5 L/min ventilation and 5 L/min cardiac output. The anesthetic partial pressure in the central nervous system (*CNS*; *purple line*), part of the vessel rich group, equilibrates rapidly with P_{alv} *(blue line)*, although a lag-time of several minutes is evident when P_{alv} is rapidly rising or falling. The anesthetic partial pressures in both muscle *(red line)* and fat *(orange line)* rise and fall much more slowly, because muscle and fat compartments represent much larger effective volumes (see Fig. 20.2) and have lower blood flow than the vessel-rich group. Note that anesthetic partial pressure in fat continues to rise after anesthetic delivery stops, as long as partial pressure in alveolar gas (and arterial blood) is greater than that in the fat compartment.

humans[26] and lab animals.[25] Recent clinical studies and mathematical modeling indicate that, because of ventilation-perfusion heterogeneity, the second gas effect is greater in arterial blood than in expired gas, influenced by the blood solubility of VAs, and significantly affects anesthetic onset at relatively low rates of N_2O uptake.[27-29]

Distribution of Anesthetic into Tissues

Blood exiting the pulmonary capillaries enters the pulmonary vein and the left heart. Inhaled anesthetics are then distributed via arterial blood to various body tissues. The rate of increase of anesthetic partial pressure within each tissue is determined by tissue-specific arterial blood flow ($\dot{q}$), effective volume (the product of anatomic volume and tissue/blood partition coefficient, $\lambda_{t/b}$), and the anesthetic partial pressure gradient between arterial blood and the tissue,

$$\frac{dP_i}{dt} = \frac{\dot{q}_i}{V_i \times \lambda_{i/b}} \times (P_{art} - P_i), \qquad (20.10)$$

where i designates a particular organ or type of tissue. Values used in model calculations are summarized in Table 20.2. The time required for anesthetic partial pressure equilibration between arterial blood ($P_{art} = P_{alv}$) and a specified tissue is shorter if its blood flow is high, and longer if that tissue has a large effective volume (Figs. 20.2 and 20.9).

Traditionally, anesthetic distribution has been described for four distinct tissue groups. The ***vessel-rich group*** (VRG) includes the heart, brain, lungs, spinal cord, liver, and kidney. Together, these organs compose approximately 10% of the adult human body mass; however, they receive approximately 70% of cardiac output under normal resting conditions. As a result, time constants for anesthetic equilibration between blood and these organs are typically only a few minutes (see Table 20.2). Of particular interest is the equilibration time for the CNS, where anesthetic effects are mediated. After the highly perfused VRG tissues, ***skeletal muscle*** is the next compartment to equilibrate with inhaled anesthetics. Muscle composes approximately 40% of body mass in a healthy adult, making muscle the largest single compartment based on weight. Moreover, most inhaled anesthetics partition into muscle more than into brain, resulting in an increased effective volume for anesthetic uptake into this compartment. At rest, muscle receives about 10% to 15% of cardiac output (20 mL/kg/min), but this value can increase dramatically during exercise, stress, fever, or other states associated with high cardiac output.[30] Taken together, these factors generally result in slow equilibration between anesthetic in blood and muscle, with typical time constants of hours (see Table 20.2). The third tissue group is ***fat***, which in a healthy adult composes less than 25% of body mass and receives approximately 10% of cardiac output.[31] Potent VAs partition avidly into fat; therefore, fat represents the largest effective volume for uptake of these drugs (see Fig. 20.2, Table 20.2). The extremely large effective volume coupled with low blood flow results in very slow equilibration of anesthetics between blood and fat, with time constants approaching days. A fourth group, including skin, cortical bone, and connective tissue, is referred to as ***vessel poor tissues***. These tissues compose 10% to 15% of an average adult body while receiving less than 5% of cardiac output at rest. Induction of general anesthesia impairs normal sympathetic nervous function, resulting in increased blood flow to normally cool skin in the extremities.[32] The blood volume represents approximately 7% of body mass and may be considered another compartment for anesthetic uptake, while also conveying drug to other tissue compartments.

As stated previously, increased cardiac output results in increased anesthetic uptake and a slower rate of rise of P_{alv}. Clinical studies confirm that, other factors being equal, increasing cardiac output slows the induction of general anesthesia with inhaled anesthetics.[21,33] This result can seem counterintuitive when increasing cardiac output increases uptake of anesthetic into the patient's body and hastens its delivery to the tissues. However, during induction, the anesthetic partial pressure in blood and downstream tissue compartments cannot be higher than that in the upstream alveolar compartment. Increased cardiac output slows the rise of P_{alv} and thus also slows the rate of increase of the anesthetic partial pressure in blood (P_{art}), the CNS (P_{CNS}), and other highly perfused tissues. The extra anesthetic uptake is primarily into muscle, which is a large tissue compartment with a high capacity for anesthetic and is where much of the excess cardiac output flows. For example, a 50% increase in cardiac output can more than double muscle blood flow, diverting the majority of anesthetic to muscle, lowering P_{alv}, and thus slowing anesthetic uptake into target tissues in the CNS. If one could manipulate inhaled anesthetic delivery to maintain constant P_{alv}, which may be achievable with automated feedback control of vaporizer output and FGF,[34] then increased cardiac output might have a different effect. Model simulations where P_{alv} is maintained at a constant level show that uptake into VRG tissues, including brain tissue, increases more rapidly as cardiac output increases.[35]

In pediatric patients, the balance of cardiac output to various tissue beds differs from that in adults. Thus, although cardiac output per kilogram body weight is larger in children than in adults, anesthetic induction in young children is more rapid than in adults, because a disproportionate amount of perfusion goes to the vessel rich organs, such as the brain.[36]

The equilibrium distribution volumes for most inhaled anesthetics are extremely large, with the largest compartment by far being fat. However, equilibration with fat is so slow that this compartment usually plays a relatively minor role in the pharmacokinetics of inhaled anesthetics. During a typical general anesthetic lasting from 30 minutes to several hours, the blood, VRG organs, and muscle are the compartments into which inhaled anesthetics mostly distribute.

Although the model in Fig. 20.2 illustrates anesthetic distribution only via arterial blood flow, ***intertissue diffusion*** takes place between abutting tissues that have large interfacial surface areas. In particular, direct diffusion from organs with high anesthetic partial pressures to abutting tissues with low partial pressure and high capacity for anesthetic uptake may also contribute to drug distribution. Examples of this process include anesthetic diffusion from the heart, liver, and kidneys to surrounding fat in the pericardium and abdomen.[37,38]

The Mixed Venous Anesthetic Partial Pressure

The anesthetic partial pressure in mixed venous blood entering the pulmonary circulation is a weighted average of the venous outflows from all tissues and organs, which converge in the right ventricle:

$$P_{MV} = \sum_{i=1}^{n} \frac{\dot{q}_i}{\dot{Q}} \times P_i. \tag{20.11}$$

As P_{MV} rises, the gradient driving uptake of inhaled anesthetics from alveoli weakens. The difference between the delivered (inspired) and the alveolar (end-expiratory) anesthetic concentrations also shrinks, causing transpulmonary uptake to slow (Eq. 20.7). *Systemic (left to right) shunting* causes P_{MV} to increase more rapidly than it would in the absence of such shunts. When blood flow to other tissues remains normal and the left-to-right shunt simply represents excess cardiac output, the resulting increase in anesthetic uptake (Eq. 20.7) is offset by the increase in P_{MV}, resulting in a slight increase in the rate of anesthetic delivery or uptake into the brain, muscle, and other tissues. In cases where large left-to-right shunts result in reduced blood flow to other tissues, anesthetic equilibration in those tissues will be relatively slow.

Synthesis of the Model and Inhaled Anesthetic Induction: PK/PD

The earlier discussion emphasized the rate of equilibration (pharmacokinetics) of inhaled anesthetics among the various compartments involved in delivery to a patient: vaporizer, circuit, lung, blood, and various tissues. However, in a clinical setting, the goal of the anesthesia provider is the reversible production of certain desired effects (amnesia, unconsciousness, and immobility) in the patient within a reasonable period of time. To achieve this goal, pharmacokinetics must be combined with knowledge of the effects produced at different anesthetic partial pressures in target tissues (i.e., dose-response or pharmacodynamics).[39] The most relevant pharmacodynamic guidelines are minimum alveolar concentration (MAC)-immobility,[40] the alveolar anesthetic concentration preventing movement response to surgical stimulus in 50% of subjects, and MAC-awake,[7] the alveolar anesthetic concentration preventing perceptive awareness in 50% of subjects, both measured under conditions where P_{alv} is in equilibrium with anesthetic partial pressure in the CNS (P_{CNS}). MAC-awake for potent VAs is typically 0.34 × MAC-immobility,[41] whereas MAC-awake for N_2O is approximately 0.7 × MAC-immobility (see Table 20.1). During induction of anesthesia, the goal may be achieving a high probability of immobility following incision ($P_{CNS} \approx 1.2 \times$ MAC-immobility) within 15 minutes, while avoiding the deleterious effects of overly deep anesthesia. At the end of an anesthetic, return of consciousness is likely to occur when P_{CNS} decreases to less than MAC-awake. The targets used for this illustrative model patient are estimates. In clinical practice, the target for depth of general anesthesia should always minimize the risk of awareness (consciousness), but may vary, depending on patient factors, the presence of noxious stimuli, and other drugs that may be administered.

There are a variety of strategies to deliver inhaled anesthetics and to achieve the desired and reversible effects of anesthesia within a reasonable timeframe. The first important consideration is that P_{del} from the vaporizer must be higher than our target P_{alv} or P_{CNS} (***overpressure***). The more overpressure used, the more rapidly anesthetic is delivered. High fresh gas flows, large MV, and a low-solubility drug will also increase the rate of anesthetic delivery and the rate of rise of P_{alv} and P_{CNS}. These factors, and particularly overpressure, also increase the risk of delivering an overdose of anesthetic drug. A common strategy is to initiate inhaled anesthetic delivery with moderate to high fresh gas flows (≥ 6 L/min) and moderate overpressure (P_{del} = 2 × MAC-immobility), and reduce P_{del} after P_{alv} reaches or slightly exceeds the target level (Fig. 20.10, left). The need to maintain overpressure and slightly overshoot P_{alv} derives from the fact that distribution of drug to muscle maintains a high delivery requirement after the initial rapid phase of uptake. If P_{del} is decreased too quickly, then P_{alv} can decrease below the target. P_{del} or FGF is slowly adjusted downward as the anesthetic inspired-to-expired difference in anesthetic partial pressures ($P_{del}-P_{alv}$) decreases.

Closed-Circuit or Low-Flow Delivery of Anesthesia

The use of high or moderate fresh gas flows, while enabling use of less overpressure, results in far more anesthetic drug being delivered than being taken up into tissues. As illustrated in Fig. 20.10C, the amount of isoflurane delivered is 4.5-fold greater than that taken up, and delivered sevoflurane is 7.2-fold greater than absorbed drug. Thus more than 80% of delivered VA is waste using the moderately

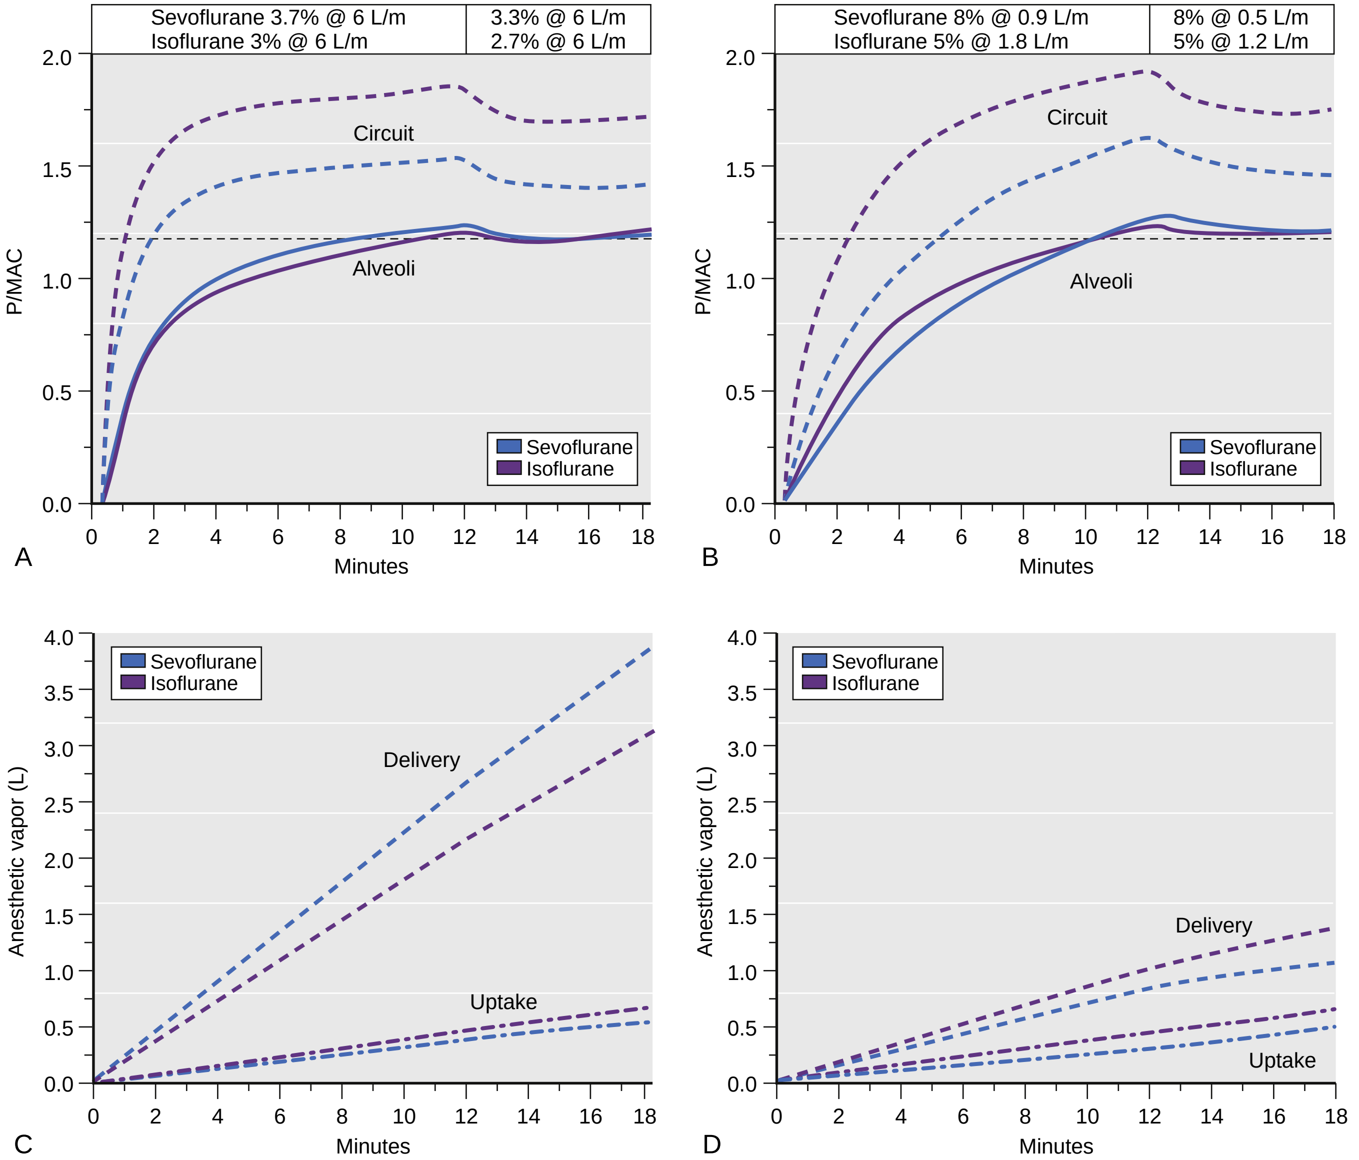

Fig. 20.10 Effect of induction technique on uptake and delivery of inhaled anesthetics. (A) Anesthetic partial pressures in both the circuit *(dashed lines)* and alveoli *(solid lines)* during inhalation induction with moderate (6 L/min) fresh gas flows and modest (twofold to threefold) overpressure for sevoflurane *(blue)* and isoflurane *(purple)*. P_{alv} reaches 1.2 × MAC in about 12 minutes, and approximately 10% downward adjustment of vaporizer settings results in maintenance of P_{alv} near this target level. Additional downward adjustments in vaporizer setting or fresh gas flows, or both, would be needed to further maintain this P_{alv} level. (B) Anesthetic partial pressures in both the circuit and alveoli during inhalation induction with low (<2 L/min) fresh gas flows and maximal (fourfold) overpressure for sevoflurane *(blue)* and isoflurane *(purple)*. P_{alv} reaches 1.2 × MAC in approximately 12 minutes, and a downward adjustment of fresh gas flow results in maintenance of P_{alv} near this target level. (C) The total anesthetic vapor delivered and taken up into the model patient from panel A. Note that delivery far exceeds uptake, more so for the low solubility anesthetic (sevoflurane). (D) The total amount of anesthetic vapor delivered and taken up into the model patient from panel B. Note that uptake is very similar to that in panel C, whereas delivery is much lower. The low fresh gas flow technique (panels B and D) reduces waste more so for anesthetics with low blood solubility (e.g., sevoflurane) than for soluble drugs (e.g., isoflurane). *MAC*, Minimum alveolar concentration; P_{alv}, alveolar anesthetic partial pressure.

high FGF approach illustrated in this example (settings are shown in Fig. 20.10*A*). Rebreathing circuits allow the use of fresh gas flows well below MV, which results in reduced anesthetic discharge into the waste-scavenging system. Less waste discharge translates into both reduced costs and reduced global environmental impact of anesthetic gases in the atmosphere, where they contribute to climate change (discussed later in this chapter). Additional benefits of low FGF and rebreathing include retention of expired heat and water vapor in rebreathed gas, improving airway epithelial health, and reducing accumulation of dried airway secretions.[42]

Closed-circuit anesthesia represents the ultimate limit of low gas flows, where fresh gases are delivered only in quantities sufficient to replace those taken up into tissues, metabolized (especially O_2), or otherwise lost to the environment, and the vast majority of gas in the breathing circuit undergoes rebreathing.[43] Achieving this goal requires a leak-free breathing circuit, complete removal of CO_2, and careful attention to the inspired-to-expired values of oxygen and anesthetic gases, and even to expired nitrogen that may slowly accumulate in the breathing circuit. Under these conditions, oxygen consumption in an anesthetized patient may be lower than 3 mL/kg/min, translating to

O_2 replacement of approximately 200 mL/min in a 70 kg patient. There are several significant limitations to this technique. Because all exhaled CO_2 must be removed by absorbents, closed-circuit anesthesia increases the risk of rebreathing CO_2 as absorbent capacity diminishes. Anesthetic breakdown products, carbon monoxide (CO), and slowly degassing nitrogen from blood can accumulate in the breathing circuit.[44] Clinicians must be aware that patient metabolism may deplete oxygen from the breathing circuit and result in delivery of a hypoxic gas mixture during use of closed circuit anesthesia. When using very low FGF values, changes in the vaporizer output (P_{del}) result in extremely slow changes in P_{circ} and the subsequent depth of anesthesia. Closed circuit anesthetic administration is often guided by the "square root of time rule," proposed by Severinghaus[45] and detailed in now classic descriptions.[46] This rule states that the rate of anesthetic uptake decreases approximately as the square root of delivery time. We can estimate the uptake of 1.2 MAC isoflurane during the first minute of anesthesia using Eq. (20.7). Thus cardiac output × $\lambda_{b/g}$ × 1.2 MAC = Initial uptake of isoflurane vapor (5000 mL/min × 1.4 × 0.0128 atm = 90 mL/min). Using the square-root of time rule, uptake at 4 minutes would be half of the initial rate (45 mL/min), and at 9 minutes, uptake would be one-third of the initial rate (30 mL/min). It should be noted that to deliver 90 mL/min of isoflurane vapor at a maximal vaporizer setting of 5% requires 1800 mL/min of FGF, far greater than the target FGF for closed circuit anesthesia. Anesthetists can overcome this limitation by directly injecting small volumes of liquid anesthetic into the expiratory limb of the breathing circuit;[47] however, this technique requires vigilant attention to the clock along with many other factors. In inexperienced hands, miscalculation or mistiming of anesthetic injection runs the risk of overdose.

Because of the challenges of closed-circuit administration, a more common practice is to use moderate to high fresh gas flows to achieve rapid changes during induction of anesthesia, reserving closed circuit anesthesia to periods where the P_{circ}−P_{alv} difference is small. Even so, changes in a patient's metabolism because of temperature variation, degree of muscle relaxation, or surgical stimulation can result in the need for frequent adjustments to oxygen flow and anesthetic depth, making anesthesia delivery in a closed circuit system relatively unstable and difficult.

Low-flow anesthetic delivery, typically with fresh gas flows of 0.5 to 1.0 L/min during the maintenance phase of an anesthetic, is a compromise between closed-circuit conditions and the use of high fresh gas flows. Much of the waste and other problems associated with high fresh gas flows are avoided, while the instability associated with a strict closed-circuit technique is also moderated. As noted earlier (see section on "Equilibration Between Circuit and Pulmonary Airspace"), the inspired anesthetic concentration (P_{circ}) depends on both P_{del} and P_{pulm} when rebreathing occurs. Thus, as FGF diminishes, P_{del} must be adjusted upward to compensate for diminished delivery. Given that the maximal output setting on most vaporizers is about 4 × MAC-immobility, anesthetic delivery at 1 L/min and maximal P_{del} is still far less than the previous example with 6 L/min and P_{del} = 2 × MAC isoflurane. Higher FGF or a less soluble anesthetic drug, or both, is needed to achieve target P_{CNS} in less than 15 minutes, but as uptake diminishes, FGF can be gradually reduced (Fig. 20.10, right panels). With soluble anesthetics like isoflurane, maximal vaporizer settings and FGF near 2 L/min is required for reasonably rapid induction. FGF can be incrementally decreased as P_{alv} reaches the target level, and eventually vaporizer output setting is decreased as well. With low solubility anesthetics like desflurane or sevoflurane, initial FGF values near 1.0 L/min can be used in combination with maximal vaporizer settings and a similar strategy of reducing FGF. These conditions result in reasonably rapid induction while minimizing waste of VAs. Low FGF can be maintained until high FGF is again needed to achieve emergence at the end of the anesthetic administration.

When using high vaporizer output settings, diligence must be maintained to avoid overdosing the patient by reducing FGF and the vaporizer setting in a timely and deliberate manner. Use of significant overpressure should be avoided in situations when other clinical issues require the attention of the anesthesia provider.

PHARMACODYNAMIC EFFECTS OF ANESTHETICS ON UPTAKE AND DISTRIBUTION

The pharmacodynamic effects of most inhaled anesthetics also include changes in ventilatory and cardiac function that thereby introduce dynamic changes in the drug pharmacokinetics. ***Spontaneous ventilation*** is reduced by inhalation of potent VAs in a dose-dependent manner.[48] As a result, spontaneously breathing patients will autoregulate to some degree by reducing their uptake of anesthetic agent as depth of anesthesia increases. This autoregulation provides a degree of safety that is absent in ventilated patients, who may be subjected to excessive delivery of inhaled anesthetics if a vaporizer is inadvertently set to deliver overpressure.[49] Inhaled anesthetics also reduce ***cardiac output***, a pharmacodynamic effect that leads to a more rapid increase in P_{alv}/P_{circ} and consequently a more rapid increase in the anesthetic partial pressure in heart, brain, and other highly perfused tissues.[50] Halothane is the anesthetic associated with the greatest reduction in cardiac output. If anesthetic delivery continues in the face of a falling cardiac output, this can lead to a positive feedback loop of worsening cardiac depression and a rapid descent toward hemodynamic collapse. More details on the effects of inhaled anesthetics on respiratory and circulatory systems are provided in Chapter 21.

THE EFFECT OF NITROUS OXIDE ON GAS-FILLED SPACES

Because N_2O is often used at high partial pressures, it diffuses into and accumulates in spaces containing air or other immobile gases, with potentially deleterious physiologic consequences. Clinically relevant examples include intravascular air emboli,[51] pneumothorax,[52] air in the inner chamber of the ear,[53] intravitreal gas bubbles,[54] intrathecal air, pneumoencephalus,[55] and air in the gastrointestinal tract.[52] Air-filled spaces contain mostly nitrogen, a gas that composes 78% of air but is 30-fold less soluble in blood than N_2O ($\lambda_{b/g}$ for N_2 is 0.015). Thus N_2O diffuses down its pressure gradient from blood and surrounding tissues into

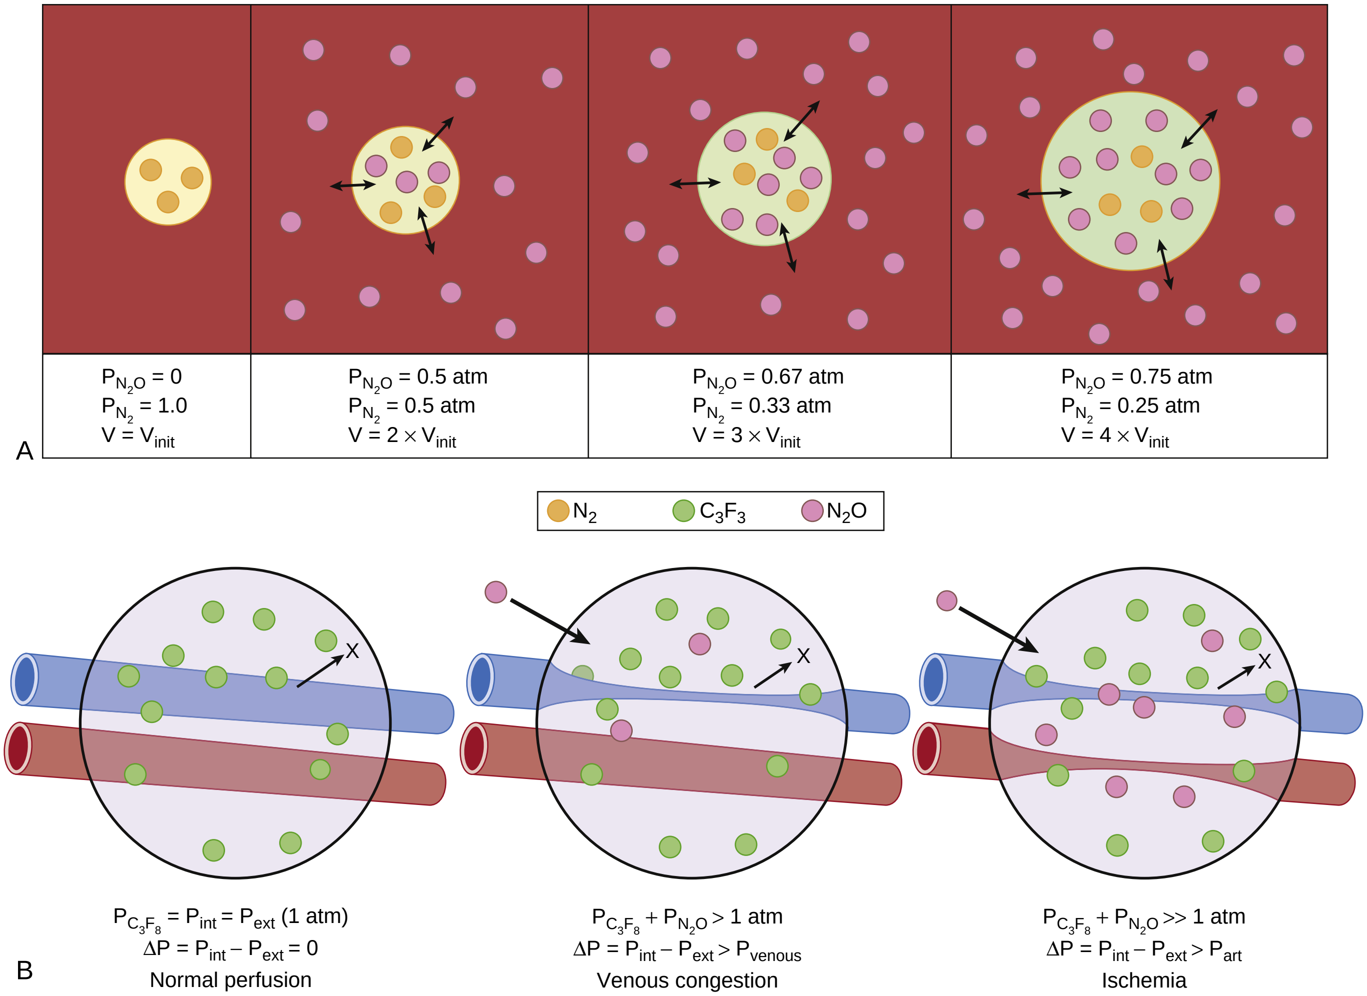

Fig. 20.11 Nitrous oxide accumulation in gas-filled spaces. A, Expansion of a compliant air-filled space (a small vascular air embolus) occurs as the partial pressure of nitrous oxide in surrounding blood increases. Each panel depicts the equilibrium condition with PN_2O inside the bubble equal to that in blood. Labels below each panel summarize the partial pressures of N_2O and N_2 in the bubble as well as the bubble volume relative to its initial value (Vinit). B, The increase in pressure inside a noncompliant, gas-filled compartment (e.g., an eye following perfluoropropane [C_3F_8] injection) with blood vessels passing through it. As N_2O accumulates, the pressure in the compartment increases, which can result in venous congestion (middle panel) or ischemia (right panel) in tissues that are perfused by the vessels in this compartment (e.g., the retina). *Atm*, Atmosphere; *ΔP*, difference between internal and external pressure; *N_2*, nitrogen; *N_2O*, nitrous oxide; *P_{art}*, arterial blood pressure; *PC_3F_8*, partial pressure of perfluoropropane; *P_{ext}*, pressure outside the compartment; *P_{int}*, internal compartment pressure; *PN_2*, partial pressure of nitrogen; *PN_2O*, partial pressure of N_2O; *P_{venous}*, venous blood pressure.

air-filled spaces, whereas N_2 elimination from these spaces is far slower, even with inspired $P_{N2} = 0$. As N_2O enters and the total number of gas molecules in an air space increases, it will expand in volume, increase in pressure, or both, depending on the compliance of the tissues surrounding the air-filled space.

In ***highly compliant air-filled spaces***, such as intravascular air bubbles or small pneumothoraces, N_2O accumulation increases the total volume of gas (Fig. 20.11*A*) with minimal changes in pressure. Air spaces expand as N_2O enters until the P_{N2O} within the air space matches that in surrounding blood, establishing equilibrium. The maximum potential gas volume expansion in a highly compliant space is

$$\frac{V}{V_{init}} = \frac{1}{1 - P_{N_2O}}. \qquad (20.12)$$

Thus administration of 50% N_2O can double air-space volume, whereas 67% can potentially triple air-space volume. N_2O can significantly worsen the cardiovascular or tissue consequences of intravascular air emboli, potentially making a nonlethal volume of venous air embolus become lethal.[51] Expansion of gastrointestinal gas volume by N_2O may impede surgical exposure or abdominal wound closure. Gas-space compartment compliance eventually decreases as volume expands, resulting in increased pressure. For example, N_2O may expand a small pneumothorax to a point where intrathoracic pressure rises, compressing lung, displacing the mediastinum, and reducing venous return (tension pneumothorax). N_2O is contraindicated in patients with intracranial air until after dural opening, in order to avoid intracranial hypertension.[56] The endotracheal tube cuff filled with air is also susceptible to expansion by N_2O. Increased tracheal cuff pressure may impair perfusion of surrounding mucosa.[57] Air-filled laryngeal mask airway cuffs[58] and the air-filled balloon of a Swan-Ganz catheter[59] may similarly expand during N_2O administration.

In ***noncompliant gas-filled spaces***, gas pressure rises as N_2O enters, until P_{N2O} within the air space matches that

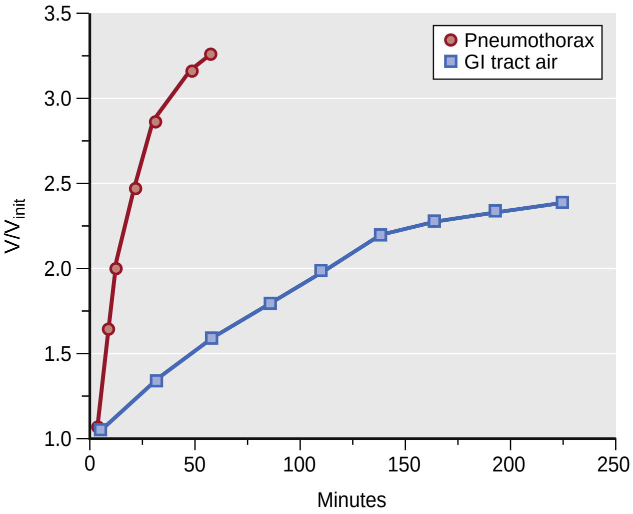

Fig. 20.12 The rate of air-space expansion during nitrous oxide administration. The rate and extent of expansion of air pockets injected into either the pleural space *(red circles)* or the gastrointestinal tract *(blue squares)* of dogs during the inhalation of a 25% oxygen/75% nitrous oxide gas mixture is shown. Air pockets in the stomach, small intestine, and colon expand more slowly than do those in a pneumothorax. *GI*, Gastrointestinal. (Data are approximations from the results reported in Eger EI II, Saidman LJ. Hazards of nitrous oxide anesthesia in bowel obstruction and pneumothorax. *Anesthesiology*. 1965;26:61–66.)

in blood. The maximal potential pressure in such a space, relative to surrounding ambient pressure, is therefore P_{N2O}. Thus, in a patient inhaling 50% N_2O, pressure in such a gas-filled compartment could approach 380 mm Hg, far greater than typical arterial perfusion pressures. A clinically important example is that of intravitreal sulfur hexafluoride (SF_6) or perfluoropropane (C_3F_8) bubbles, which are injected as the sclera is closed at the end of intraocular or retinal surgery (see Fig. 20.11*B*).[54] These gases persist even longer than N_2 does, because of their low blood solubility. If N_2O is administered to these patients at the time of intravitreal bubble injection, its diffusion into the bubble can rapidly increase intraocular pressure above that in retinal veins, producing retinal congestion. If the pressure in the eye further increases above systolic arterial pressure, retinal ischemia resulting in blindness may ensue.

The ***rate of N_2O diffusion into gas-filled spaces*** in the body depends on local blood flow and the surface to volume ratio of the space. Thus small air emboli expand within seconds, because they have high surface/volume ratios and are surrounded by a very high relative flow of blood containing dissolved N_2O. Larger air emboli expand more slowly, because their surface/volume ratios are smaller (spherical surface/volume is inversely proportional to radius). Small pneumothoraces typically have large surface/volume ratios and high local blood flow. Animal experiments show that inhalation of 75% N_2O approximately doubles pneumothorax volume in 10 minutes and triples it in 30 minutes (Fig. 20.12). Compared with a pneumothorax, gastrointestinal air pockets have lower surface/volume ratios and lower blood flow. Thus expansion of gas in the gastrointestinal tract is much slower than that in a pneumothorax. In animal studies (see Fig. 20.12), inhalation of 70% to 80% N_2O doubled intestinal gas volume after approximately 2 hours.[52]

N_2O use is contraindicated in patients with pneumothorax, pneumocephalus, and closed dura, or in those at high risk for vascular air embolus. Air-space expansion may impede surgery when substantial gastrointestinal air is present and N_2O exposure is prolonged, or it can be of little consequence when the initial volume of gas in the gut is small or when the surgery is brief.

RECOVERY FROM ANESTHESIA

Similarities and Differences to Induction

Clearance of inhaled anesthetics from target tissues (brain and spinal cord) is primarily via the same pathways used for anesthetic induction: anesthetic gases flow from tissue into venous blood and then to the lungs. If P_{alv} is less than P_{MV}, then the net flow of anesthetic will be out of the blood and into alveoli, where it is subsequently exhaled. To achieve the fastest clearance possible, P_{circ} must therefore be as low as possible, and this is achieved using high flows of nonanesthetic carrier gases (oxygen and air) after discontinuing delivery of anesthetic. The same factors that affect transalveolar anesthetic exchange during induction will also affect clearance via this route. Increasing ventilation will accelerate clearance (see Fig. 20.4), whereas increased cardiac output slows clearance, because more gas-exchange volumes are required to remove anesthetic from the larger blood flow (see Fig. 20.5). Highly blood-soluble anesthetics, which increase the *effective* blood flow, clear more slowly than insoluble anesthetics (see Fig. 20.6). Return-to-consciousness, which usually occurs after P_{CNS} decreases below MAC-awake, is faster following desflurane or sevoflurane anesthesia than after isoflurane anesthesia. N_2O, which is characterized by blood solubility similar to that of desflurane, provides an even faster return to consciousness, because of two additional advantages. First, the concentration effect works in reverse during clearance of N_2O, increasing effective alveolar ventilation and maintaining the gradient for flow from pulmonary blood to alveoli. Second, MAC-awake for N_2O (0.71 atm at 40 years old) is near typical inhaled concentrations during general anesthesia; therefore, elimination of only a small fraction of this drug is associated with return to consciousness. This is also why N_2O as the sole hypnotic drug is associated with a high risk of intraoperative awareness, which can be prevented by using a balanced gas mixture of N_2O together with end-tidal concentrations of about 1 × MAC-awake of a second potent inhaled anesthetic.

Body composition has an increasing impact as the length of anesthetic exposure increases, especially for highly soluble anesthetics. Compared with standard models, patients with increased muscle or fat will have larger volumes of anesthetic drug distribution over time, resulting in slower clearance rates.[60] One important difference between anesthetic uptake and clearance is that although overpressure can be utilized to hasten uptake and induction of anesthesia, the vaporizer setting cannot be set to less than zero. As a consequence, the most readily modifiable factors to affect the rate of anesthetic clearance are fresh gas flow and MV. Indeed, after prolonged (>4 hours) exposure to 1 × MAC inhaled anesthesia, maintenance of adequate ventilation should be a high priority, even after end-tidal anesthetic concentrations reach MAC-awake. Hypoventilation in this

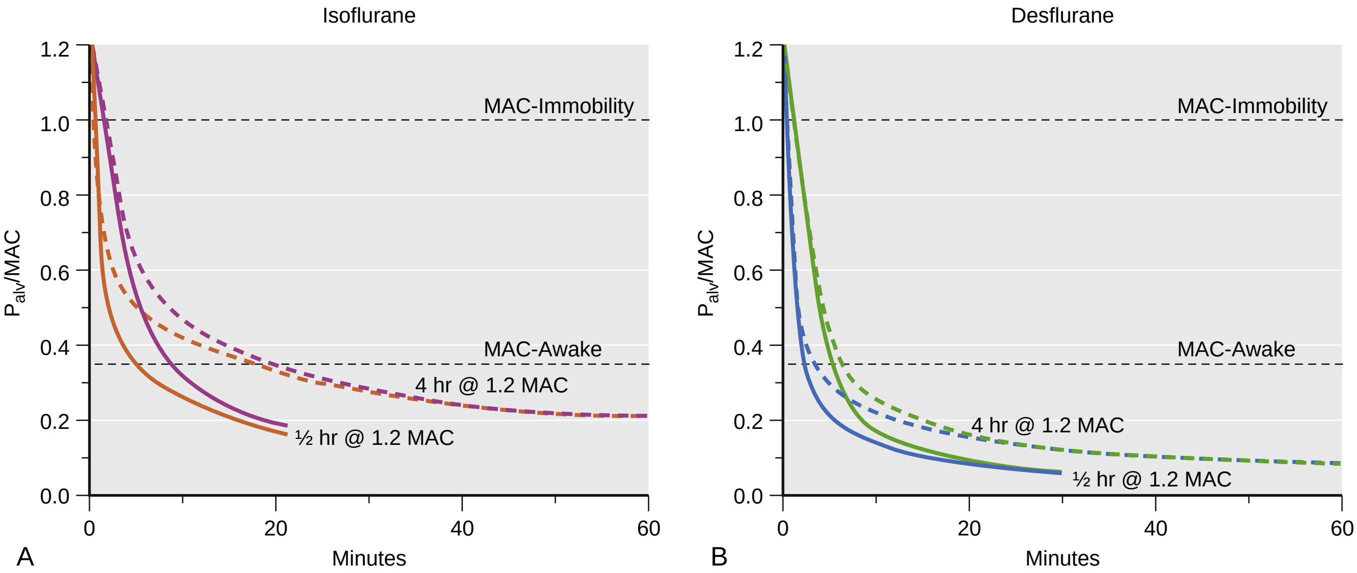

Fig. 20.13 Inhaled anesthetic wash-out and time to awakening depends on duration of anesthesia. The panels depict model calculations of P_{alv} and P_{CNS} normalized to MAC during wash-out at 10 L/min FGF and 5 L/min MV following anesthesia at approximately 1.2 × MAC-immobility for 30 minutes *(solid lines)* or 4 hours *(dashed lines)*. The MAC-awake (approximately 0.34 × MAC-immobility) is shown to indicate the threshold below which typical patients regain perceptive awareness after general anesthesia. Although P_{alv} drops earlier than P_{CNS}, the clinically relevant endpoint (return of consciousness) is predicted when P_{CNS} falls below MAC-awake. (A) Wash-out using a pharmacokinetic model for isoflurane (orange is P_{alv}, purple is P_{CNS}). The 30-minute isoflurane uptake was 990 mL of vapor, and the 4-hour isoflurane uptake was 3420 mL of vapor. Prolonged anesthesia with isoflurane dramatically increases the time required to wash-out sufficient drug to achieve awakening. After a 30-minute anesthetic, P_{CNS} (solid purple line) drops to MAC-awake in 9 minutes, whereas it takes more than 20 minutes of wash-out to reach the same P_{CNS} following a 4-hour anesthetic (dashed purple line). (B) Wash-out using a desflurane model (blue is P_{alv}, green is P_{CNS}). The 30-minute desflurane uptake was 1530 mL of vapor, and the 4-hour desflurane uptake was 4600 mL of vapor. The predicted times to awakening (solid versus dashed green lines reach MAC-awake at 5.2 and 6.3 minutes, respectively) are much closer following different durations of desflurane anesthesia, because of its low blood solubility. Clinical studies demonstrate that emergence and recovery (time to extubation) following isoflurane anesthesia nearly doubles when exposure increases from 20 to 75 minutes, whereas extubation is achieved in less than 10 minutes following desflurane anesthesia from 20 to 100 minutes' duration.[63] *FGF*, Fresh gas flow; *MAC*, minimum alveolar concentration; *MV*, minute ventilation; *P_{alv}*, Alveolar anesthetic partial pressure; *P_{CNS}*, anesthetic partial pressure in the central nervous system.

situation can result in reanesthetization caused by redistribution of anesthetic drug from muscle into blood and highly perfused tissues.[61]

Context Sensitive Recovery from Anesthesia

Although the concept of context sensitive half-time is typically applied to continuously infused anesthetics that distribute among multiple pharmacokinetic compartments, it also applies to inhaled anesthetics.[62] After a short period of inhalation and uptake, anesthetic clearance from blood is rapid through both exhalation and distribution to muscle and other tissues. As a result, P_{alv} decreases rapidly to a low value after discontinuing anesthetic delivery. After prolonged periods of inhalation and uptake, the anesthetic partial pressures in muscle and other compartments increase closer to that in blood, reducing the contribution of distributive clearance. Instead, clearance from the central blood compartment is slowed by the reverse flow of anesthetic from the high-capacity tissues. Thus, in comparison with a short period of inhalation, prolonged inhaled anesthesia is followed by a smaller initial decrease in P_{alv} and a more pronounced slow clearance phase, resulting in slower recovery from anesthesia (Fig. 20.13).[63] As with other factors, context sensitivity is exaggerated in highly soluble anesthetics, and it has less impact with anesthetics that display low blood and tissue solubilities.[63] The relative advantage of low blood solubility anesthetics increases with the duration of anesthesia. There is only a small (2.5 minutes) difference between predicted times to awakening after a short anesthetic with isoflurane versus desflurane, but significantly faster awakening can be achieved using the low-solubility drug for long cases.

Percutaneous and Visceral Anesthetic Loss

Aside from pulmonary exchange, some portion of inhaled anesthetics is lost by diffusion through other large area interfaces between the body and surrounding air. The skin surface area of an average human is about 2 m^2, and blood flow through skin during general anesthesia may be substantial because of inhibition of normal thermoregulatory vasoconstriction.[32] Nonetheless, transcutaneous losses of general anesthetics probably contribute negligibly to their clearance.[64,65] During open abdominal or thoracic surgery, visceral surfaces are also directly exposed to air, and under these circumstances, anesthetic losses via direct transfer and air movements are larger than those via skin, but still a small fraction of total clearance.[66]

Effect of the Anesthetic Circuit

As mentioned earlier, circuit components, including tubing, connectors, manual ventilation bag, and CO_2 absorbent material, absorb inhaled anesthetics, effectively creating another compartment that fills while anesthetic is flowing, and needs to be emptied during wash-out.[19] Low-level release of anesthetic gases from these components can continue for a considerable time.

Clearance via Metabolism of Anesthetics

Metabolism of inhaled anesthetics in tissues, particularly liver, contributes a variable degree to drug clearance. Metabolism of inhaled anesthetics is reviewed in detail in the second part of this chapter (see section on "Metabolism and Toxicity of Inhaled Anesthetics"). Methoxyflurane, a drug that is no longer in clinical use, and halothane, an older drug that is rarely used in the United States, are highly metabolized inhaled anesthetics. Methoxyflurane undergoes extensive metabolism in humans, with only 19% of an inhaled dose recovered in exhaled gases.[67] Approximately 20% to 25% of inhaled halothane is metabolized through biotransformation in the liver. A high rate of metabolism will reduce the anesthetic partial pressure in tissues, resulting in reduced P_{MV} and increased rates of overall anesthetic clearance. Tissue-dependent breakdown contributes less to clearance of newer inhaled anesthetics.

Additional Considerations and Possibilities

Modern inhaled anesthetics like sevoflurane and desflurane have low blood solubility, and therefore provide a distinct advantage for both anesthetic induction and recovery from anesthesia. However, they present no advantage over older drugs like isoflurane for maintenance of anesthesia during long cases and are far more expensive. What if anesthesia is induced with one drug, followed by a switch to isoflurane during the maintenance period, and then switched back to the more soluble drug, such as desflurane, for a period preceding emergence? This might allow for more rapid induction and wakeup than with isoflurane alone. Although a fast wakeup can be achieved by allowing sufficient time for near total washout of isoflurane and its replacement with desflurane, this type of crossover requires significant lead time and high fresh gas flows. As an illustration, Neumann and colleagues[68] compared 2-hour anesthetics at 1.25 × MAC (2 L/min FGF) with isoflurane alone, desflurane alone, or isoflurane with a crossover to desflurane during the last half hour. Although subjects awoke faster with desflurane alone, the crossover strategy did not result in acceleration of wakeup compared to isoflurane alone.

Diffusion Hypoxia

Diffusion hypoxia is another sequelae of rapid outgassing from the tissues of patients anesthetized with N_2O. During the initial 5 to 10 minutes after discontinuation of anesthesia, the flow of N_2O from blood into the alveoli can be several liters per minute, resulting in dilution of alveolar oxygen.[69] Another effect of rapid outgassing is reduction of alveolar P_{CO_2}, which may also reduce respiratory drive.[70] If the patient does not receive supplemental oxygen during this period, then the combined effects of respiratory depression from anesthesia, reduced alveolar P_{CO_2}, and reduced alveolar P_{O_2} can result in hypoventilation and oxyhemoglobin desaturation. This outcome is avoided by routinely providing supplemental O_2 for the first 5 to 10 minutes of recovery, together with vigilant attention to respiration and oxygenation.

Metabolism and Toxicity of Inhaled Anesthetics

This portion of the chapter focuses on adverse effects that are attributable to inhaled anesthetics, excluding most of the acutely reversible pharmacodynamic effects of inhaled anesthetics on various physiologic systems (see Chapters 11, 14, and 21).

The inhaled anesthetics are a unique group of drugs that can both enter and leave the body unchanged through the lungs. Thus chemical transformation of inhaled anesthetics is unrelated to their therapeutic activities such as amnesia, hypnosis, and immobilization. Nonetheless, the carbon-halogen and other bonds of volatile alkanes and ethers can break down under certain conditions: biotransformation by enzymes in various tissues, reactions with strong bases in CO_2 absorbents, and exposure to ultraviolet radiation in the environment. Anesthetic breakdown resulting from decomposition in tissues or the breathing circuit can produce toxic reactive intermediates, which in sufficient amounts can harm patients directly or indirectly. N_2O gas is not biotransformed, but selectively reacts with and inactivates vitamin B_{12} and perturbs B_{12}-dependent biochemical pathways. The breakdown of waste anesthetics in the atmosphere also has potential environmental and health consequences. There are potential long-term neurotoxic effects of anesthetic exposure in patients that are not associated with chemical breakdown. Potential neurotoxic properties of inhaled anesthetics are further described in Chapters 78 and 84.

BIOTRANSFORMATION OF INHALED ANESTHETICS

The extent and location of inhaled anesthetic metabolism depends on multiple chemical factors. Inhaled anesthetics undergo varying degrees of biotransformation (Table 20.3)[71] in various tissues. Methoxyflurane undergoes by far the greatest metabolism, estimated at 70%, and experiments indicate that only a small fraction of drug taken up into body tissues is exhaled.[67] Given the remarkable lipophilicity of methoxyflurane, respiratory clearance of this drug from muscle and fat extends over a period of days (see Tables 20.1 and 20.2). Halothane is the next most lipophilic drug and ranks second in metabolic clearance (see Table 20.3).[72-96] Thus prolonged residence in body tissues is an important factor in biotransformation of inhaled anesthetics. Chemical stability is another important factor. Isoflurane is an isomer of enflurane, and the two drugs display comparable respiratory uptake, distribution, and respiratory clearance. Nonetheless, isoflurane is metabolized only one tenth as much as enflurane. Although sevoflurane and desflurane represent another pair of anesthetics, both are characterized by rapid uptake, distribution, and respiratory clearance with 5% of sevoflurane biotransformed versus 0.02% of desflurane.

Of the major organs involved in anesthetic biotransformation, the liver and kidneys are exposed to the highest metabolite concentrations and thus are also most susceptible to damage from toxic metabolites. Clinically significant hepatotoxicity is primarily associated with exposure to halothane, and nephrotoxicity is associated with methoxyflurane.[71] Investigations into the mechanisms of these toxicities have influenced drug development and also provided important insights into human toxicology.[97]

TABLE 20.3 Metabolism of Halogenated Volatile Anesthetics

Anesthetic	Halothane	Methoxyflurane	Enflurane	Isoflurane	Desflurane	Sevoflurane

Biotransformation in the Liver

The liver is the major site of metabolism for most drugs, particularly lipophilic drugs, which typically are transformed into hydrophilic metabolites that are more readily excreted. The liver is large and contains high concentrations of many drug-metabolizing enzymes. Other organs that contribute to drug metabolism and clearance include the gastrointestinal tract, kidneys, and lungs.[98,99] Drug biotransformation reactions include oxidation, hydrolysis, and conjugation. A single drug may be transformed into several metabolites, depending on the relative rates of various enzyme reactions, the drug concentration in different tissues expressing relevant enzymes, competition at enzyme sites with other drugs or endogenous substances, and other factors. Oxidation and hydrolysis are also known as *phase 1 reactions*, and they result in the introduction or exposure of a polar group on the drug. The phase 1 enzymes that metabolize inhaled anesthetics in the liver are various cytochrome P450 (CYP) isoforms in the endoplasmic reticulum of hepatocytes. These catalyze oxidation reactions such as dehalogenation, N- and O-dealkylation, N- and S-oxidation, and deamination. These reactions require oxygen and NADPH-dependent cytochrome P450 reductase as cofactors. Under hypoxic conditions, some P450 enzymes can also catalyze reductive reactions. More than 50 CYP isoforms are active in humans, and CYP3A4 and CYP3A5 are the most abundant. Conjugations are also known as *phase 2 reactions*, and they often append highly polar groups such as glucuronic acid, sulfate, or glycine to polar groups on phase 1 metabolites. The resulting hydrophilic products are readily excreted in urine via the kidneys or in bile via the gastrointestinal tract. N-Acetylation reactions are an exception that result in metabolites that are less water-soluble than the parent drug.

Many factors affect hepatic drug metabolism, including concomitant drugs, disease, age, and genetics.[100] Induction and inhibition of enzymes are associated with exposure to certain drugs or other exogenous substances. Induction of specific CYP isoforms is a gene-mediated response to chronic exposure to substances that often are substrates of the enzyme, resulting in accelerated enzyme production or slowed turnover. For example, phenobarbital use results in increased production of CYP3A4 as well as NADPH-cytochrome P450 reductase, leading to dramatically increased metabolism of all CYP3A4 substrates. Enhanced metabolism can reduce drug efficacy (and therefore is one mechanism of drug tolerance) or, in cases of prodrug transformation to active metabolites, increased efficacy. If metabolites are toxic, as is the case with VAs, enhanced metabolism may increase toxicity. Conversely, CYP inhibition leads to enhanced activity of parent drugs and reduced metabolite effects. CYP enzyme inhibition is associated with hepatic disease and exposure to certain substances. An important example is CYP3A4 inhibition by grapefruit juice.[100] Regarding VAs, the major oxidative enzyme CYP2E1 is inducible by ethanol and isoniazid and is inhibited by disulfiram.[101] Diseases such as hepatitis, various cirrhotic diseases, and hepatocarcinoma can also reduce enzymatic activity, as can cardiac failure with reduced hepatic perfusion.

Neonates have different dominant CYP isoforms than adults. Impaired hepatic metabolism is common in premature and full-term infants, notably in bilirubin glucuronidation, leading to hyperbilirubinemia of the newborn.[102,103] Pharmacogenomics is a growing area of pharmacologic research that has linked variable drug metabolism to genetic variability. A well-established example in anesthesiology is homozygous inheritance of atypical butyrylcholinesterase,

resulting in slow hydrolysis of succinylcholine.[104] Genetic variations in CYP2D6 have clarified the basis for widely varying efficacies and toxicities of codeine (a prodrug), metoprolol, nortriptyline, dextromethorphan, and other substrate drugs.[105]

Hepatic CYP2E1 is particularly important in the oxidative metabolism of halogenated inhaled anesthetics (see Table 20.3). Under conditions of systemic hypoxia or decreased blood flow, or in liver regions of low P_{O_2}, CYP2A6 and CYP3A4 catalyze breakdown of VAs via reductive pathways. Halothane metabolism is primarily oxidative, and under normal conditions, about 1% of halothane undergoes reductive metabolism. Oxidative metabolism of halothane releases chloride and bromide ions, resulting in trifluoroacetyl chloride, which reacts with water to form trifluoroacetic acid (Fig. 20.14). Reductive metabolism of halothane results initially in loss of bromide, and the intermediate either reacts with a hydrogen donor to form 2-chloro-1,1,1-trifluoroethane or captures an electron, further reducing the carbon-carbon bond to form 2-chloro-1,1-difluoroethylene (see Fig. 20.14). Halothane reduces hepatic blood flow and can cause hepatocellular hypoxia in some regions in the liver, potentially leading to an increase in its reductive metabolism.[71] All of the ether anesthetics undergo similar oxidative metabolism catalyzed by CYP2E1 (see Table 20.3, Fig. 20.15). Oxidative metabolism of these drugs results in the release of fluoride (F^-) and chloride (Cl^-) ions and the formation of reactive intermediates that react with water to form carboxylic acids. Isoflurane and desflurane both produce trifluoroacetic acid, whereas enflurane forms 2-difluoromethoxy-2,2-difluoroacetic acid. Oxidative metabolism of methoxyflurane may follow several paths, releasing either Cl^- or F^- in sequential steps and producing methoxy-difluoroacetic acid, dichloroacetic acid, and acetic acid (see Table 20.3).

Halothane Hepatotoxicity

The first modern halogenated VA, halothane, was introduced in 1955. Clinical exposure to halothane is associated with two distinct types of hepatic injury.[76,106,107] Subclinical hepatotoxicity occurs in 20% of adults who receive halothane. It is characterized by mild postoperative elevations in alanine aminotransferase (ALT) and aspartate aminotransferase (AST), but is reversible and innocuous. Anaerobic halothane reduction by CYP2A6 to a 2-chloro-1,1,1-trifluoroethyl radical (see Fig. 20.14) is thought to mediate this mild hepatic injury.[72] The fulminant form of hepatotoxicity, commonly known as halothane hepatitis, is characterized by elevated ALT, AST, bilirubin, and alkaline phosphatase levels, and massive hepatic necrosis following the administration of halothane. Halothane hepatitis is rare (1 in 5000-35,000 administrations in adults) but is fatal in between 50% to 75% of cases. Because of the potential for fatal hepatitis, halothane is no longer used in adult patients in most countries.

Halothane hepatitis is caused by a hypersensitivity reaction associated with oxidative metabolism of halothane. The highly reactive trifluoroacetyl chloride metabolite of halothane oxidation can react with nearby liver proteins (see Table 20.3). In most patients who developed hepatic necrosis after halothane anesthesia, antibodies against trifluoroacetyl-modified proteins were detected, suggesting that the hepatic damage is linked to an immune response against the modified protein, which acts as a neoantigen (Fig. 20.16). Accordingly, patients who develop halothane hepatitis often have a history of prior exposures to halothane or other VAs, together with symptoms suggestive of immune reactivity, such as fever, rash, arthralgia, and eosinophilia.[75] It is hypothesized that trifluoroacetyl-protein adducts induce a cytotoxic T-cell reaction in sensitized individuals, which leads to liver damage.[76] However, definitive evidence that liver injury is immune-mediated in halothane hepatitis is lacking.

Hepatotoxicity and massive hepatic necrosis after halothane anesthesia also occurs in children. However, two large retrospective studies have demonstrated that the clinical syndrome of halothane hepatitis is even more rare in pediatric patients (1 in 80,000-200,000) than in adults.[108-110] Halothane is metabolized to a similar degree in adults and children, and children are immune competent from birth. Pediatric cases of halothane hepatitis are also associated with multiple anesthetic exposures, suggesting a mechanism similar to that in adults. Why the incidence of halothane hepatitis is significantly higher in the adult population remains unknown.

Other VAs including enflurane, isoflurane, and desflurane have also been associated with fulminant hepatic necrosis,[92,111-115] but compared with halothane, the incidence of

Fig. 20.15 Proposed pathways for inhaled anesthetic metabolism to reactive intermediates. CYP2E1 catalyzes oxidative metabolism of halothane, enflurane, isoflurane, and desflurane to a variety of reactive intermediates that can form adducts with hepatocellular proteins. Trifluoroacetylated proteins are identical after halothane, isoflurane, and desflurane, whereas adducts following enflurane are immunologically similar.

Fig. 20.16 Pathways generating the immune response after exposure to inhaled anesthetics. Halothane is metabolized to a reactive trifluoroacetyl intermediate that forms an amide bond with hepatocellular proteins. The altered protein triggers an immune response, which on subsequent exposure to anesthetic results in hepatocellular damage and necrosis. A similar process may ensue after exposure to other fluorinated drugs metabolized to similar halo-acyl intermediates. TFA, Trifluoroacetic acid. (Modified from Njoku D, Laster MJ, Gong DH, et al. Biotransformation of halothane, endflurane, isoflurane and desflurane to trifluoroacetylated liver proteins: association between protein acylation and liver injury. *Anesth Analg*. 1997;84:173–178.)

this potentially fatal toxicity is very rare after administration of these newer VAs. The mechanism of severe hepatitis following enflurane, isoflurane, and desflurane may be the same as for halothane, because all of these drugs are oxidatively metabolized to highly reactive intermediates that can covalently modify hepatic proteins (see Fig. 20.15). As with halothane, case investigations usually reveal that patients have had prior exposure to VAs, and antibodies to modified hepatic proteins can be detected. The extremely infrequent incidence of severe hepatitis for modern VAs is likely because of their lower degree of oxidative metabolism and subsequent immune sensitization. In fact, hepatitis was also commonly reported soon after introduction of methoxyflurane, another anesthetic that is mostly metabolized to highly reactive acidic intermediates.[77,116] Unlike all other VAs, sevoflurane is oxidized at the fluoromethoxy C-H bond and forms hexafluoroisopropanol and inorganic F^- (see Table 20.3; Fig. 20.17).[117,118] Hexafluoroisopropanol is relatively stable, and modified liver proteins are not formed after sevoflurane anesthesia. Cases of hepatitis and rapid death after sevoflurane anesthesia have been reported, but there was no evidence of an immune-mediated mechanism.[96]

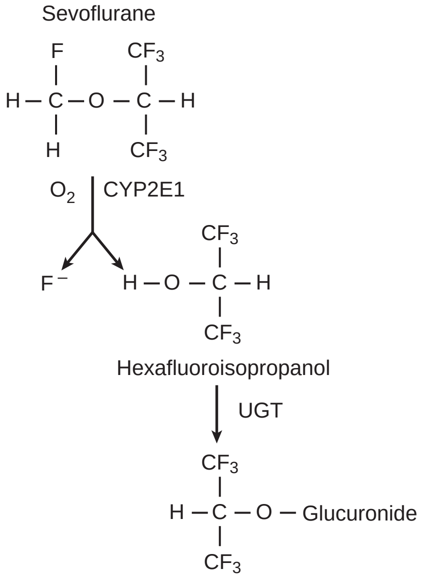

Fig. 20.17 Metabolic oxidation of Sevoflurane. CYP2E1 catalyzes phase 1 defluorination of sevoflurane, forming hexafluoroisopropanol. Phase 2 glucuronidation is catalyzed by uridine 5′-diphosphate glucuronosyltransferase (UGT).

Biotransformation in Kidneys

The kidneys are large organs that receive high blood flow. Renal physiologic activities include glomerular filtration of water-soluble metabolites, reabsorption of water and essential metabolites, urinary excretion of waste, and regulation of hormones involved in vascular tone (renin) and water balance (aldosterone). The kidneys clear most of the water-soluble metabolites resulting from biotransformation of inhaled anesthetics. Kidneys also contain CYP enzymes, including CYP2E1, that catalyze both phase 1 and phase 2 reactions and are therefore additional sites where inhaled anesthetic metabolism occurs. As in the liver, various CYPs in renal parenchyma may undergo induction or inhibition by exogenous substances.[119-122]

Fluoride-Associated Nephrotoxicity

The first modern halogenated ether anesthetic, methoxyflurane was introduced in 1959. Methoxyflurane causes polyuric renal insufficiency and is no longer used in clinical practice.[123] The nephrotoxic effect of methoxyflurane is attributed to inorganic fluoride (F^-) released during its metabolism. Investigations have provided significant insights into potential nephrotoxic mechanisms by fluorinated VAs and have influenced the development of subsequent halogenated anesthetic agents.

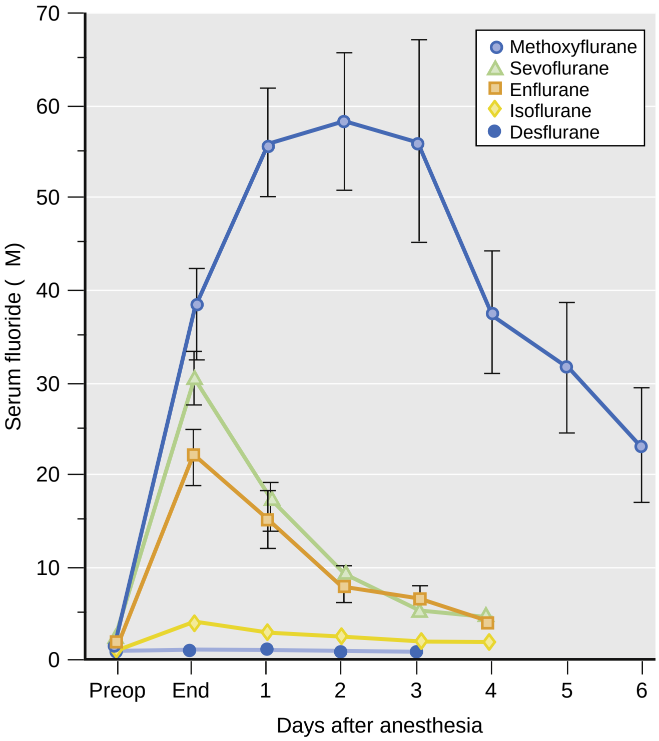

Fig. 20.18 Serum inorganic fluoride (F^-) exposure during and after methoxyflurane anesthesia is much greater than with other anesthetics. Points represent serum F^- measurements (mean ± SD) from multiple subjects. After 2 to 3 MAC-hours of methoxyflurane anesthesia, F^- rises during and after drug administration ends, peaks above 60 μmol/L on postanesthesia days 2 and 3, then declines slowly, remaining elevated for more than 1 week. Sevoflurane anesthesia (3.7 MAC-hours) produces an early peak F^- concentration averaging 31 μmol/L, which declines over 3 to 4 days. Enflurane anesthesia (2.7 MAC-hours) results in an early average peak of 22 μmol/L that declines in 3 to 4 days. Isoflurane and desflurane result in small and negligible rises in serum F^- concentrations. Only methoxyflurane is associated with fluoride-associated renal toxicity. *MAC*, Minimum alveolar concentration (immobility).

Absorbed methoxyflurane undergoes extensive biotransformation,[67] including cytochrome-catalyzed oxidation that releases inorganic fluoride ions (F^-) into blood. Animal studies provide clear evidence of the nephrotoxicity of methoxyflurane, which includes a strong relationship between methoxyflurane dose and renal injury,[124] increased nephrotoxicity with induction of CYP enzymes,[125,126] and decreased nephrotoxicity with inhibition of methoxyflurane metabolism.[84,127] Clinical data further indicate that severity of nephrotoxicity and mortality are associated with high plasma fluoride concentrations after methoxyflurane anesthesia.[128,129] Patients with serum inorganic fluoride levels below 50 μM had no evidence of renal injury, whereas patients with postmethoxyflurane serum F^- greater than 50 μM suffered high rates of renal dysfunction and increased mortality.[79,130] Moreover, serum F^- concentrations were significantly higher after the administration of methoxyflurane than with other halogenated VAs, which are not associated with nephrotoxicity (Fig. 20.18). Inorganic fluoride released during methoxyflurane metabolism probably causes renal injury, and the nephrotoxic threshold for plasma F^- is approximately 50 μM. Individual variability among patients in the degree of apparent renal injury after methoxyflurane exposure was observed. Genetic heterogeneity, drug interactions, and preexisting renal disease likely account for these differences.

Since the introduction of methoxyflurane, all prospective halogenated anesthetic agents have been extensively tested experimentally and clinically for their degree of defluorination and the resulting serum F^- concentrations. However, experience with newer drugs, particularly with sevoflurane, has caused investigators to reexamine the classical fluoride-induced nephrotoxicity hypothesis. Sevoflurane was initially synthesized in the 1970s, but because of its relatively large defluorination rate (2%-5%), its introduction into clinical practice was delayed. It was first widely used

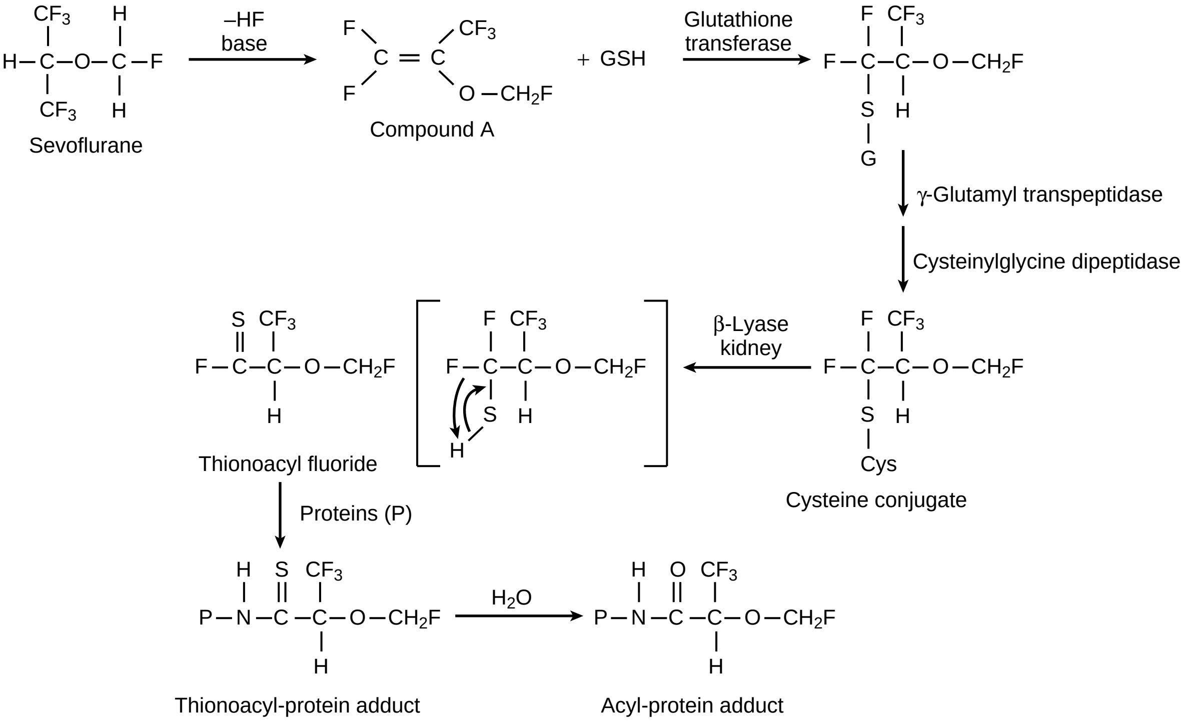

Fig. 20.19 Proposed pathway mediating nephrotoxic effects of compound A in rodents. Sevoflurane degrades to compound A in the presence of strong base in some CO_2 absorbent materials. Compound A itself is not nephrotoxic but undergoes hepatic S-conjugation with glutathione. In the kidney, additional metabolic steps produce a S-cysteine compound A conjugate, which is metabolized by β-lyase to a reactive thionoacyl fluoride that is proposed to damage proteins essential for kidney function. Humans have very low β-lyase activity, which is hypothetically the basis for the lack of reported nephrotoxicity in patients. *CO_2*, Carbon dioxide; *GSH*, glutathione; *HF*, hydrofluoric acid. (Adapted from Martin JL, Kandel L, Laster MJ, et al. Studies of the mechanism of nephrotoxicity of compound A in rats. *J Anesth*. 1997;11:32–37.)

in Japan in 1990. Subsequent clinical studies demonstrated no clinically significant nephrotoxicity after the administration of sevoflurane, even when the high peak blood F^- concentrations greater than 50 μM were confirmed.[117] Typical peak fluoride concentrations after 2 to 3 MAC-hours of sevoflurane anesthesia are 20 to 30 μM, and less than 5 μM after isoflurane and desflurane (see Fig. 20.18). Enflurane metabolism also often results in peak blood F^- concentrations greater than 20 μM. Isoflurane and desflurane are minimally metabolized and produce lower plasma fluoride concentrations. However, none of these anesthetics is associated with clinically significant renal toxicity, suggesting that methoxyflurane is unique in its ability to harm kidneys. One important difference between methoxyflurane and current VAs is its extreme lipophilicity and extremely long residence time in tissues. This results in prolonged elevated F^- concentrations in blood (see Fig. 20.18), suggesting that the length of F^- exposure is a key risk factor. However, prolonged moderate elevations of plasma fluoride (25-38 μM) during several days of isoflurane anesthesia without adverse renal effects have been documented.[131,132] Thus neither the peak level nor the duration of high plasma fluoride concentration entirely explains the nephrotoxic effects by the halogenated anesthetics. It is also not clear whether the integrated concentration multiplied by time exposure to inorganic F^- represents the key risk factor. However, methoxyflurane is metabolized to a large extent within kidney parenchyma, producing high intrarenal inorganic fluoride concentrations (likely much higher than those measured in blood), which are proposed to cause renal injury.[78,80] Thus, compared with methoxyflurane, the absence of renal toxicity with newer volatile halogenated agents likely derives from a combination of factors: (1) their lower tissue solubilities, particularly in kidney (see Table 20.2), resulting in lower intrarenal fluoride production; (2) lower overall degrees of biotransformation; and (3) more rapid respiratory clearance from the body.

ANESTHETIC DEGRADATION IN CARBON DIOXIDE ABSORBENTS

Sevoflurane, Compound A, and Renal Toxicity

Halogenated anesthetics can undergo chemical breakdown while interacting with carbon dioxide (CO_2) absorbents that contain strong bases such as sodium hydroxide (NaOH) and potassium hydroxide (KOH), which are present in soda lime and Baralyme.[133] Strong bases extract a proton from the isopropyl group of sevoflurane, primarily forming a haloalkene [fluoromethyl-2,2-difluoro-1-(trifluoromethyl) vinyl ether], known as *compound A* (Fig. 20.19). Compound A is volatile and can be absorbed via alveolar gas exchange. Compound A exposure is nephrotoxic in laboratory animals, causing proximal tubular necrosis and, with sufficient exposure, death. In rats, renal injury is observed with cumulative exposure to compound A above 150 parts per million (ppm)-hours (e.g., 50 ppm inhalation for 3 hours).[134,135] Moderately severe but reversible histopathologic damage was found in rats after 200 ppm-hour exposure, associated with increased blood and urea nitrogen (BUN), creatinine, and other measures of renal damage. Compound A exposure over 1000 ppm-hours is lethal in half of exposed rats.

Patients receiving sevoflurane anesthesia are routinely exposed to compound A in rebreathing circuits, and the inhaled concentration is dependent on the fresh gas flow rate and the type of CO_2 absorbent present. Fresh gas flows of 1 L/min result in maximal compound A concentrations around 20 ppm with soda lime and 30 ppm with Baralyme.[136] Higher FGF rates result in less compound A accumulation in the breathing circuit. However, compound A exposure is not associated with clinically significant nephrotoxicity in humans. There is no threshold exposure level known to cause more than subclinical renal damage. Numerous studies in which human subjects or patients were exposed to more than 200 ppm-hours of compound A have reported that clinical measures of renal function (BUN, creatinine, urinary protein or glucose, and urine concentrating ability) and laboratory tests for subtle renal damage (N-acetyl-β-glucoaminidase, alanine aminopeptidase, γ-GTP, and β2-microglobulin) remain unchanged.[81,86,137-139] Kharasch and colleagues[140] compared the effects of low-flow sevoflurane and isoflurane anesthesia in patients with stable renal insufficiency, and found no significant difference in postoperative renal function tests. Other studies have reported normal BUN and creatinine, but transient reversible abnormalities in other renal function test values following prolonged sevoflurane anesthesia at low FGF (>330 ppm-hour compound A exposure in one study).[141-144]

The evidence of nephrotoxicity in rats compared with the remarkably benign results in humans suggests that mechanisms of sevoflurane metabolism and toxicity differ between these species. The difference in the nephrotoxic effects of compound A between humans and rats may be attributed to the doses of compound A, interspecies differences in metabolic toxification, and sensitivity of the proximal tubular cells to compound A cytotoxicity.[71] Detailed studies show that in rats, compound A undergoes S-conjugation to cysteine, and that the resulting cysteine conjugate is metabolized by renal β-lyase to form a reactive thionoacyl fluoride intermediate that acylates proteins and has been proposed to mediate the nephrotoxic effect (see Fig. 20.19).[133,145] Human kidneys have far lower β-lyase activity than rat kidneys, accounting for the differential toxicity of compound A in the two species. Experiments testing whether inhibition of β-lyase with aminooxy-acetic acid (AOAA) protects rats from compound A nephrotoxicity have had mixed results.[146,147] Alternative mechanisms underlying compound A toxicity have been proposed, including formation of reactive sulfoxides catalyzed by CYP3A isozymes,[148] which are also more active in rat than human kidneys.

Although the mechanism underlying compound A toxicity in laboratory animals remains uncertain, the lack of significant sevoflurane nephrotoxicity in human clinical data is reassuring. Compound A exposure can be limited by careful selection of fresh gas flows, vaporizer output, and CO_2 absorbent materials. The use of 2 L/min fresh gas flows assures that for the vast majority of patients, exposure to compound A will be below the most conservative threshold for nephrotoxicity. Although clinical studies indicate that sevoflurane is most likely safe, even in patients with preexisting renal dysfunction, the drug should be administered in accordance with the approved package labeling guidelines.

Like sevoflurane, halothane degrades in the presence of CO_2 absorbents to form a reactive intermediate, bromochlorodifluoroethylene (BCDFE),[133] which has also been investigated as a possible nephrotoxin. Eger and colleagues[149] found that in comparison to compound A, BCDFE accumulates 20- to 40-fold less in breathing circuits and is 4-fold less reactive. Thus the risk of BCDFE nephrotoxicity is negligible.

TABLE 20.4 Composition of Base Chemicals and Water Content of Carbon Dioxide Absorbents

Comparison of Amsorb, sodalime, and Baralyme degradation of volatile anesthetics and formation of carbon monoxide and compound A in swine in vivo. *Anesthesiology*. 2002;96:173–182.

Carbon Monoxide and Heat

In the presence of strong bases in dry CO_2 absorbents (water content <5%), some halogenated VAs undergo degradation, resulting in the formation of CO, trifluoromethane (CF_3H), and hydrogen fluoride (HF).[133] The factors that determine the amount of CO produced include the chemical makeup of CO_2 absorbent (KOH > NaOH >> $Ba(OH)_2$, $Ca(OH)_2$), dryness of the absorbent material, the concentration of volatile agent, and its chemical structure.[150] Baralyme contains 4.6% KOH, whereas soda lime contains 2.5% KOH and 1.3% NaOH, and reacts less vigorously with halogenated anesthetics. The relatively weak bases $Ba(OH)_2$ and $Ca(OH)_2$ are other major constituents in CO_2 absorbents, and do not catalyze CO formation (Table 20.4).[136,151] The anesthetics that contain a difluoromethyl group (difluoromethyl-ethyl ethers) are most susceptible to this degradation, and for these drugs CO production correlates with anesthetic concentration in the breathing circuit (desflurane > enflurane > isoflurane)[152] (Fig. 20.20).[152] Sevoflurane, methoxyflurane, and halothane also degrade in the presence of strong bases, but do not produce CO. Production of CO appears to require nearly complete desiccation (i.e., removal of moisture) of the CO_2 absorbent, and typically occurs after high-flow "flushing" of the breathing circuit for 1 to 2 days. Soda

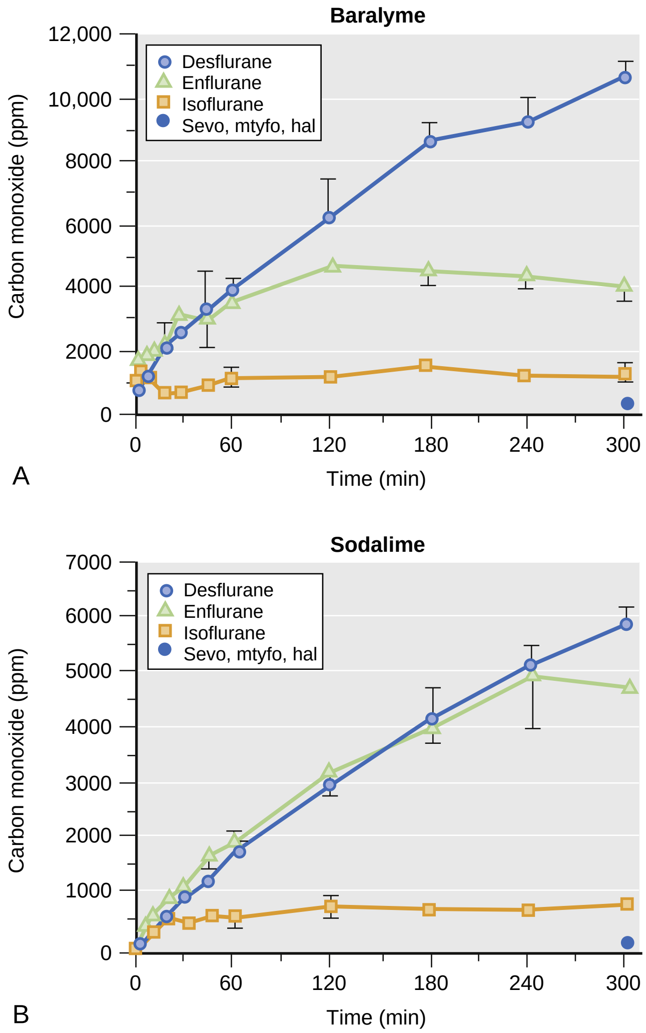

Fig. 20.20 Inhaled anesthetic degradation and carbon monoxide production. Points represent mean ± SD of three measurements with equivalent anesthetic doses (1.5 × MAC) in the presence of dry CO_2 absorbents at identical fresh gas flows. (A) Degradation and CO production with Baralyme. (B) Degradation and CO production with soda lime. Degradation and CO production was observed with anesthetics containing difluoromethoxy groups (desflurane, enflurane, and isoflurane), but not halothane *(hal)* or those with monofluoromethoxy groups such as sevoflurane *(sevo)* and methoxyflurane *(mtyfo)*. *CO,* Carbon monoxide; *MAC,* minimum alveolar concentration. (Adapted from Baxter PJ, Garton K, Kharasch ED. Mechanistic aspects of carbon monoxide formation from volatile anesthetics. *Anesthesiology*. 1998;89:929–941.)

lime contains 15% water by weight, and Baralyme contains 13% water by weight (see Table 20.4). CO production is observed when the water content of soda lime or Baralyme falls below 1.4% and 5%, respectively.[153] High ambient temperatures also accelerate desiccation of CO_2 absorbent materials and may increase the rate of CO producing reactions. As noted with compound A, CO accumulation in the breathing circuit is inversely related to the fresh gas flow.

Anesthetic degradation in the breathing circuit has resulted in CO poisoning during clinical anesthesia.[154,155] CO has 250-fold greater affinity for hemoglobin than O_2 does; therefore, the formation of carboxyhemoglobin reduces blood oxygen carrying capacity and tissue oxygen delivery, and is difficult to reverse. The detrimental effects and signs of CO toxicity are well known. However, during general anesthesia, signs of patient exposure to CO are masked and hypoxia may be difficult to detect because most pulse oximetry equipment cannot distinguish between carboxyhemoglobin and oxyhemoglobin.

The degradation of VAs by bases in CO_2 absorbents is an exothermic reaction that results in the production of heat. Sevoflurane produces the most heat when it is used with desiccated CO_2 absorbent. The absorbent canister and anesthetic circuit can reach extremely high temperatures, which can lead to explosion or fire, or both.[156,157]

Current recommendations to minimize anesthetic degradation to CO and heat include machine maintenance measures to avoid desiccation of CO_2 absorbents and the use of absorbents that contain less KOH and NaOH. Newer CO_2 absorbents (see Table 20.4) contain little or no strong base and do not degrade VAs, regardless of hydration status.[136,158,159] The use of the newer CO2 absorbents also reduces the production of compound A during sevoflurane anesthesia.[160–162]

NITROUS OXIDE, VITAMIN B12, AND HOMOCYSTEINE

N_2O is unique among anesthetics in irreversibly inhibiting cobalamins (vitamin B12) by oxidizing the Co (I) ligand. Cobalamins are ingested or produced by bacteria in the gut and are critical cofactors together with 5-methyltetrahydrofolate in the activity of methionine synthase (Fig. 20.21). Methionine synthase catalyzes methylation of homocysteine to methionine, while demethylating 5-methlytetrahydrofolate to tetrahydrofolate. Methionine, converted to S-adenosylmethionine, is the major substrate for methylation in biochemical pathways involved in the synthesis of DNA, RNA, myelin, and catecholamines[163] Chronic vitamin B12 deficiency (as in pernicious anemia) results in hematologic and neurologic dysfunction. Long-term N_2O exposure, typically among individuals who frequently inhale it as a recreational drug, can also cause megaloblastic anemia, myelopathy (subacute combined degeneration), neuropathy, and encephalopathy, sometimes presenting as psychosis.[164–167] N_2O is the eighth most commonly used recreational substance in the United Kingdom.[168] Risk factors that increase susceptibility to N_2O toxicity include pernicious anemia or other gastrointestinal malabsorption syndromes, extremes of age, alcoholism, malnutrition, a strict vegetarian diet, and inborn deficiencies in cobalamin or tetrahydrofolate metabolism.[164] Inhibitors of folate metabolism, such as methotrexate, may also enhance sensitivity to N_2O toxicity.[169]

In healthy surgical patients, megaloblastic changes in the bone marrow are rare, and reported only after a prolonged period of exposure (>12 hours) to N_2O. Healthy pediatric patients exposed to N_2O for up to 8 hours during spine surgery do not develop evidence of megaloblastic anemia.[170] However, in seriously ill patients or those with risk factors noted earlier, shorter (or repetitive) periods of N_2O exposure may lead to significant subacute pathology. Megaloblastic bone marrow changes can be induced after a short period (2-6 hours) of N_2O exposure.[171] Vitamin B12 deficiency or reduced methionine synthase activity can also lead to subacute myelopathy and neuropathy.[172-175] A case highlighting the potential importance of inborn

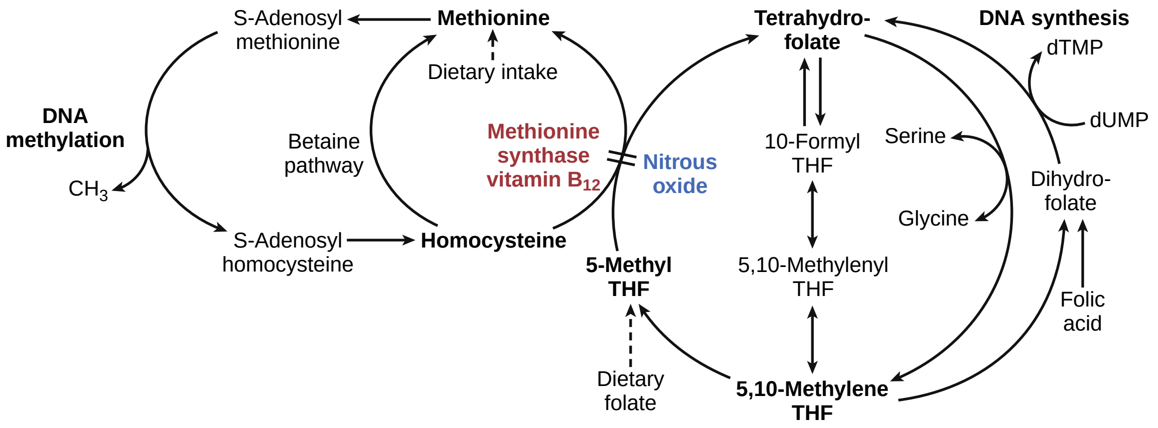

Fig. 20.21 Nitrous oxide inhibition of methionine synthase. Biochemical cycles involved in methylation reactions are shown. Methionine synthase *(red)* catalyzes methylation of homocysteine with 5-methyl tetrahydrofolate as the donor, producing methionine and tetrahydrofolate *(THF)*. Both vitamin B12 and folate are essential cofactors for methionine synthase. Nitrous oxide *(blue)* inhibits methionine synthase by oxidizing the cobalt of cobalamin (vitamin B_{12}). Methyl transfer pathways are important in synthesis of protein and DNA. *dTMP*, Deoxythymidine; *dUMP*, 2′-Deoxyuridine 5″-Monophosphate.

metabolism was reported by Selzer and colleagues.[176] In this case, a 4-month-old child developed an irreversibly and ultimately fatal seizure disorder several weeks after receiving N_2O during anesthesia. Autopsy revealed widespread brain atrophy and demyelination, and biochemical investigations revealed reduced methyltetrahydrofolate reductase (MTHFR) activity, which eventually were linked to several mutations in the gene encoding MTHFR.

Another consequence of reduced methionine synthase activity is accumulation of its substrate: homocysteine (see Fig. 20.21). Homocystinuria caused by severe inborn deficiency of methionine synthase activity is associated with extremely elevated blood homocysteine levels, early atherosclerosis of coronary and cerebral arteries, and premature death.[177] These observations led to the “homocysteine hypothesis,” which postulates that homocysteine stimulates inflammation and atherosclerosis, and is a key modifiable factor in vascular morbidity and mortality. Despite some evidence that increased homocysteine levels are an independent risk factor for cardiac and cerebrovascular morbidity,[178,179] the association between homocysteine levels and atherothrombotic disease is weak, as some large prospective studies have found.[180] Moreover, studies in which diet and vitamin supplementation was used to reduce homocysteine levels demonstrate improvement in some markers of vascular risk, but do not reduce the rate of myocardial infarction and atherosclerotic stroke.[180,181] Thus it appears that the importance of chronic *moderate* elevation in homocysteine to cardiovascular outcomes is tenuous, or perhaps only pertinent to limited patient populations.

Does the rapid increase of homocysteine levels during N_2O anesthesia influence the risk of cardiovascular and neurovascular morbidity following surgery and anesthesia? Badner and colleagues[182] reported that N_2O administration significantly increased homocysteine levels and increased myocardial risk in carotid endarterectomy patients. The Evaluation of Nitrous Oxide in a Gas Mixture for Anaesthesia (ENIGMA) trial in more than 2000 patients reported that avoidance of N_2O combined with increased inspired oxygen concentration during anesthesia decreased the incidence of a variety of complications after major surgery, but found no reduction in death, myocardial infarction, stroke, or hospital length of stay.[183] In a follow-up study of the ENIGMA trial, patients reported that those exposed to N_2O for more than 2 hours were at increased risk (odds ratio 1.6; 95% confidence interval, 1.01-2.5) of myocardial infarction up to 5.7 years after enrollment.[184] No difference in rates of death or stroke were found. Unfortunately, diagnosis of myocardial infarction in ENIGMA was often based on data obtained in telephone interviews, rather than established diagnostic criteria. However, a follow-up randomized trial in 7112 patients (ENIGMA-II) reported no difference in myocardial infarction, stroke, pulmonary embolism, or cardiac arrest risk within 30 days of surgery.[185] A recent post hoc study of 5133 enrollees in the Perioperative Ischemic Evaluation (POISE) trial[186] also found no increase in rates of death, myocardial infarction, or stroke in approximately 1500 patients who received N_2O.

Anecdotally, N_2O use is thought to contribute to myocardial infarction in patients with elevated homocysteine levels at baseline.[187] Homocysteine elevation following N_2O inhalation is a useful marker for assessing the sensitivity of methionine synthase and related biochemical pathways to N_2O inhibition. Nagele and colleagues[188] studied a small group of surgical patients with common mutations in the gene encoding MTHFR, and found that those with 667C→T and 1298A→C mutations were at risk of developing abnormally high homocysteine levels after N_2O exposures of at least 2 hours. However, a common gene variant (66A→G) associated with reduced methionine synthase reductase activity did not result in abnormally high homocysteine levels after anesthesia with N_2O[189] Preoperative infusions of vitamin B12 and folate do not prevent the normal elevation in homocysteine observed following anesthesia with N_2O.[190]

The continued value of N_2O, first used as an anesthetic in the early 19th century, has been questioned by some who view its known and potential toxicities as outweighing benefits such as rapid onset and offset and relative cardiovascular stability during anesthesia.[191,192] Currently available data indicate that N_2O does not alter the risk of cardiovascular morbidity in the vast majority of patients. The authors recommend careful screening of patients to identify the few most likely to suffer N_2O toxicity, and to avoid the drug in these cases.

TABLE 20.5 Atmospheric Lifetimes and Environmental Effects of Inhaled Anesthetics

Compound		Lifetime (years)	Ozone-Depleting Potential	Global Warming Potential (20 years)	Global Warming Potential (100 years)
CFC-12	CCl_2F_2	100	1	11,000	10,900
Carbon dioxide	CO_2	5-200	–§	1	1
Nitrous oxide	N_2O	114	0.017[212]	289	298
Halothane	$CF_3CHBrCl$	7[213]	0.36	–	218
Isoflurane	$CHF_2OCHClCF_3$	2.6-3.6[214]	0.01	1230-1401[214]	350
Sevoflurane	$CH_2FOCH(CF_3)_2$	1.2-5.2[214]	0	349-1980[214]	575
Desflurane	$CHF_2OCHFCF_3$	10[214]	0	3714[214]	–

Ozone depleting potential (ODP) is the ratio of integrated perturbations to total ozone relative to an equal emission of CFC-12. Global warming potential (GWP) is defined as the cumulative radiative retention integrated over a period of time from the emission of gas relative to reference gas (Carbon Dioxide). The data are based on the Intergovernmental Panel on Climate Change (IPCC) Fourth Assessment Report[215] unless otherwise indicated. § CO_2 unlikely reacts and depletes ozone. However, CO_2 producing the greenhouse effect in the troposphere is predicted to reduce stratospheric temperatures and cause further ozone depletion.[216] Computed value for halothane relative to GWP for CFC-12.

INHALED ANESTHETICS AND NEUROTOXICITY

For a comprehensive description of potential neurotoxic properties of inhaled anesthetics, see Chapter 78.

The ability of general anesthetics to reversibly ablate consciousness has benefitted millions of patients and enabled dramatic advances in health care. While inhaled agents were the first class of anesthetics and continue to be used in the vast majority of cases, accumulating evidence suggests potential long-lasting neurotoxic effects of inhaled and other general anesthetics in patients of extreme ages (see Chapter 78).[193,194] The greatest concern surrounds the impact of general anesthetics in the youngest patients during periods of rapid brain development. In a seminal study, Jevtovic-Todorovic and coworkers[195] demonstrated widespread neuronal death (apoptosis) in the brains of 7-day-old rats after exposure to midazolam, isoflurane, and N_2O, associated with long-lasting (up to 4.5 months) changes in neurophysiological correlates of learning and memory, and performance deficits in spatial learning tests. Other animal studies in various species, including nonhuman primates, demonstrate that during sensitive periods of early brain development, exposure to most general anesthetics is associated with accelerated neuronal apoptosis and degeneration.[196-200] Neonatal primate studies suggest that exposure to anesthetics for as little as 3 hours leads to neuro-apoptosis and neurocognitive problems.[197,199,201] Other studies suggest that low nonapoptotic concentrations of general anesthetics may inhibit normal synapse formation and damage developing neuronal networks.[202] Mechanisms underlying neurodevelopmental toxicity are potentially linked to the same ion channels hypothesized to mediate general anesthesia. General anesthetic actions are attributed in part to both antagonism of N-methyl-D-aspartate (NMDA) receptor and potentiation of $GABA_A$ receptor signal transduction, and drugs with either or both of these activities damage developing brains.[194,203,204]

Based on preclinical studies showing that anesthetic exposure consistently impairs neurodevelopment, the US Food and Drug Administration (FDA) issued a safety announcement that repeated or lengthy exposures to general anesthetics and sedative drugs before the age of three have the potential to harm the development of children's brains (http://www.fda.gov/drugs/drugsafety/ucm532356.htm). Emerging clinical data, however, indicate either no or very modest associations between exposure to surgical procedures requiring general anesthesia and neurodevelopmental outcomes.[205–208] The Pediatric Anesthesia NeuroDevelopment Assessment (PANDA) trial compared a cohort of children who received general anesthesia for hernia repair before age 3 with siblings.[209] The neuropsychological outcomes showed no difference between groups. A randomized clinical study, the General Anesthesia Compared to Spinal Anesthesia (GAS) trial, compared infants who underwent hernia repair with awake-spinal versus inhaled general anesthesia. At age 2, cognitive scores in the two groups were equivalent,[210] whereas the primary outcome at age 5 has not been reported. Related clinical studies exploring a variety of long-term outcomes in children are underway, adding uncertainty to clinical decision making. A comprehensive examination of this topic is provided elsewhere in this textbook ("Pediatric Anesthesia," Chapter 78). For updated recommendations to healthcare providers and parents regarding exposure to anesthesia and surgery in early life, please consult https://smarttots.org/about/consensus-statement/. For a comprehensive description of long-term cognitive effects of surgery and anesthesia in adults, see Chapter 84.

INHALED ANESTHETICS AND ENVIRONMENTAL EFFECTS

Anesthetic gases in the workplace and in the outdoor environment have the potential to cause harm. An American Society of Anesthesiologists (ASA) Task Force released a comprehensive document on environmentally sustainable anesthesia practice, including the choice of anesthetic gases and reduction of waste: https://www.asahq.org/resources/resources-from-asa-committees/environmental-sustainability/greening-the-operating-room.[211] Three potential sequelae have been investigated: global warming, ozone depletion, and health effects from workplace exposure (Table 20.5).[212–216]

Global Warming Effects

Atmospheric trapping of thermal radiation from the Earth's surface is known as the *greenhouse effect*, which the

Intergovernmental Panel on Climate Change[217] deems a major contributor to global warming. Inhaled anesthetics are recognized greenhouse gases.[218,219] Isoflurane, sevoflurane, and desflurane, the most widely used current inhaled anesthetics, are minimally metabolized in the body and are substantially eliminated through exhalation. Most anesthesia waste scavenging systems transfer these gases directly and unchanged into the atmosphere, which has drawn attention to the ecotoxicologic properties of inhaled anesthetics. The global warming potential (GWP) takes into account the heat-trapping efficiency and life-span of atmospheric gases (i.e., the time for removal by chemical reaction with radicals, photolysis, and deposition). The GWP of halogenated anesthetics is reported to range from 1230-fold (isoflurane) to 3714-fold (desflurane)—that of an equal mass of CO_2. Ryan and Nielsen[214] suggested that the most common VAs can significantly influence global warming, with the greatest impact produced by atmospheric desflurane.[214]

The GWP of N_2O is approximately 300-fold greater than that of an equal mass of CO_2.[220,221] N_2O is administered to patients in much larger quantities relative to VA gases and is remarkably stable, with an atmospheric life-span of approximately 120 years.[222] Atmospheric N_2O is produced by natural sources in soil and water, as well as human sources, including agriculture (nitrogen-based fertilizers) and combustion of fossil fuels. Sherman and Cullen[223] first reported that N_2O could contribute to global warming and estimated that approximately 1% of man-made N_2O production was for anesthesia. Anesthetic use may contribute 3.0% of total N_2O emissions in the United States.[219] Although the use of N_2O is declining in many countries, data on the worldwide medical use of N_2O are not available.

Ozone Depletion

The ozone layer of the Earth's atmosphere, which has been declining 4% per decade since the 1970s, absorbs damaging ultraviolet B light (UVB; wavelengths 280-315 nm). The biologic consequences of increasing UVB radiation include increases in skin cancer, cataracts, damage to plants, and reduction of oceanic plankton populations. Halogenated VAs are similar to chlorofluorocarbons (CFCs), which are major ozone depleting pollutants. Ozone depletion by halocarbons depends on molecular weight, number and type of halogen atoms, and atmospheric life-span.[224] The atmospheric life-span of halogenated anesthetics is much shorter (4.0-21.4 years)[225] than that of many CFCs (up to 100 years). Fluorination is associated with longer atmospheric life-span because of the stability of carbon-fluorine (C-F) bonds. Chemicals with a lifetime of more than 2 years are believed to reach the stratosphere in significant quantities. There they are exposed to intense ultraviolet radiation that can break carbon-halogen bonds, creating halogen radicals that catalytically destroy ozone. Chlorine-containing anesthetics such as halothane, isoflurane, and enflurane may be more destructive to the ozone layer than sevoflurane and desflurane, which contain only C-F bonds. Carbon-hydrogen bonds are susceptible to attack by hydroxyl radicals (OH) in the troposphere,[226] making them less likely to reach the stratosphere. However, even compounds with a lifetime of a few months may potentially contribute to ozone destruction.[227] Contributions to total stratospheric ozone depletion were estimated as 1% for halothane and 0.02% for enflurane and isoflurane.[225]

N_2O is the primary source of stratospheric nitrogen oxides, NO and NO_2, and both destroy ozone. Because only 10% of N_2O is converted to NO_X, its ozone depleting potential is lower than that of an equal mass of CFCs. However, N_2O emission is reported to be the single largest ozone depleting human emission, and is expected to remain so for the rest of this century. [212] The use of N_2O could actually contribute additional environmental harm when used with halogenated anesthetics.

The environmental impact of all inhaled anesthetics could be reduced by 80% to 90% if closed circuit anesthesia is widely employed, and to a lesser degree if low carrier gas flow rates are routinely used (see Fig. 20.13). Technologies that trap anesthetics in waste gas flows have the potential to reduce emissions into the environment, and can reduce drug costs by reusing (after redistillation) the trapped drugs.[228] Physician education warning that the medical use of N_2O can significantly contribute to both the greenhouse effect and ozone depletion should be maintained. Avoiding N_2O when it provides no clinical advantage is suggested for a more environmentally sound anesthetic practice.[218]

Exposure to Waste Anesthetic Gases

Healthcare personnel can be exposed to waste anesthetic gases both in and out of the operating room environment. Possible adverse health effects by chronic exposure to trace concentrations of inhaled anesthetics has concerned healthcare professionals for many years.[229,230] Laboratory studies suggest reproductive abnormalities in animals exposed to high concentrations of N_2O (1000 ppm or greater).[231,232] Long-term occupational exposure to anesthetic gases may be associated with genomic alterations.[233] However, a long-term prospective study found no causal relationship between adverse health effects and exposure to waste anesthetic gases with or without a scavenging system.[234]

All inhaled anesthetics cross the placental-fetal exchange barrier. Teratogenicity, which has been demonstrated in animal fetuses chronically exposed to N_2O,[235,236] is of particular concern in pregnant healthcare workers, but there is no evidence of harm in humans. Furthermore, there is no definitive evidence of harm to fetuses of women anesthetized while pregnant,[237] although studies are underway addressing the possibility that anesthetics cause harm during critical phases of fetal brain development (see earlier section, "Inhaled Anesthetics and Neurotoxicity," and Chapter 78).[238] The US Occupational Safety and Health Administration (OSHA) recommends that no worker should be exposed to concentrations of halogenated anesthetic greater than 2 ppm for a period exceeding 1 hour during anesthesia administration (http://www.osha.gov/dts/osta/anestheticgases/index.html). OSHA also recommends that no worker should be exposed to 8-hour time-weighted average concentrations of N_2O greater than 25 ppm.

Potential postoperative exposure of healthcare workers to exhaled anesthetic gases in postanesthesia care units, intensive care units, and other patient care areas should also be recognized. Studies have documented excessive levels of waste anesthetic gases in poorly ventilated postanesthesia care areas.[239-241] However, no studies have documented significant adverse health effects.

Xenon and Other Noble Gases

Modern inhaled anesthetics represent vast improvements over earlier inhaled agents, with N_2O representing the longest surviving widely used anesthetic. The noble gas xenon was first shown to produce general anesthesia in 1951,[242] and subsequent studies have revealed that in comparison with other inhaled anesthetics, it approaches being the ideal agent.[243-245] It is most comparable to N_2O, but superior in a number of ways. Xenon is present as a minor constituent of air (50 parts per billion), and is isolated by distillation of liquefied air, along with liquefied nitrogen and oxygen. Xenon is entirely unreactive in the biosphere and is the only inhaled anesthetic that is not an environmental pollutant, although its distillation from air uses considerable energy and thus creates CO_2 and other pollutants as byproducts.[219] It is odorless, tasteless, nonflammable, and has a limitless shelf-life. Its solubility in blood ($\lambda_{b/g} = 0.14$) and body tissues is lower than that of any other inhaled anesthetic, including N_2O. As a result, it has extraordinarily rapid onset and respiratory clearance, with emergence times 2- to 3-fold faster when it replaces N_2O in clinical settings.[246-248] It undergoes no biotransformation or reactions with CO_2 absorbents or ultraviolet light. Moreover, xenon has favorable pharmacodynamic effects in comparison to most inhaled anesthetics. It produces minimal cardiovascular depression and is not arrhythmogenic.[248-251] As with N_2O, xenon has analgesic activity and reduces intraoperative opioid requirements.[252] It does not trigger malignant hyperthermia or produce any known toxicity.[253] In fact, xenon has been shown to have cardioprotective and neuroprotective activities in preclinical models.[243,245] Clinical trials in adult cardiac surgery patients,[254-256] partial nephrectomy patients,[257] and comatose survivors of cardiac arrest[258,259] have demonstrated that xenon reduces pressor requirements and modestly reduces the extent of organ damage, relative to other anesthetics. However, in these clinical settings and in others, xenon does not improve neurocognitive function or survival.[260-262]

Given all these advantages, why is xenon not a commonly used inhaled anesthetic? The main reason is its cost.[263] At more than $15/L in the gas form, xenon is greater than 100-fold more expensive than N_2O and far more expensive per patient than either desflurane or sevoflurane, which are currently the most expensive VAs. Xenon has a MAC-immobility of 0.61 atm, and even with a strict closed-circuit technique, greater than 10 L are needed to anesthetize a typical patient. To perform closed circuit anesthesia with xenon-oxygen also requires lengthy preanesthetic denitrogenation to prevent N_2 from accumulating in the rebreathing circuit.[264] Transitioning from 100% oxygen during denitrogenation to closed circuit xenon-oxygen anesthesia is another slow process because xenon is added to the circuit as oxygen is metabolized in the patient at 200 to 250 mL/min. High-flow xenon is otherwise necessary to make this transition short. To make xenon a more affordable anesthetic, specialized anesthesia machines have been designed to enable its efficient delivery,[265] and new waste-scavenging systems are being introduced with cryogenic traps that can condense xenon in a liquid form from waste gases.[266] This process allows relatively inexpensive recycling of xenon after it has been redistilled to a pure form.

In addition to cost, xenon presents a few other downsides. Xenon gas has a much higher density (5.9 g/L) than either N_2O (1.9 g/L) or air (1.2 g/L), resulting in increased flow resistance and work of breathing.[267] Thus it may be a poor choice for patients with compromised respiratory function. As with N_2O, high xenon partial pressures needed for anesthesia cause expansion of trapped air spaces and vascular air emboli.[268] Compared with propofol infusion or sevoflurane inhalation, xenon anesthesia results in a higher incidence of nausea and vomiting.[269,270]

Currently, xenon remains an experimental anesthetic, with clinical research focusing on its potential as an organ protectant, and the development of technologies to reduce its cost. Shifting the cost-benefit balance toward more xenon use in patients will depend on whether clinical studies end up supporting xenon's beneficial efficacy. Other noble gases also share some of xenon's neuroprotective actions in experimental model systems and are also under investigation as potential clinical anesthetics.[271]

Pulmonary Pharmacology and Inhaled Anesthetics

OLEG V. EVGENOV, YAFEN LIANG, YANDONG JIANG, and
JAMES L. BLAIR

KEY POINTS

- Inhaled anesthetics affect every part of physiology of the lungs and their pulmonary pharmacology is complex.
- Volatile anesthetics produce bronchodilation through decreases in cytoplasmic ionized calcium concentration and/or a reduction in calcium sensitivity of airway smooth muscle. Volatile anesthetics also attenuate an increase in pulmonary airway resistance induced by chemical and mechanical stimulation.
- Inhaled anesthetics reduce the rate of mucous clearance and affect function of type II alveolar cells; these effects can potentially contribute to postoperative pulmonary complications.
- Volatile anesthetics produce a biphasic response in pulmonary vascular smooth muscle. Although inhibition of hypoxic pulmonary vasoconstriction by volatile anesthetic is an overall small effect, it can contribute to worsening of hypoxemia in patients with underlying pulmonary disease.
- Volatile anesthetics depress respiratory function through a diminished respiratory drive and an increase in upper airway collapsibility. Following extubation, even at residual concentrations, volatile anesthetics can severely impair peripheral chemoreceptor inputs and hypoxic arousal reflexes.
- Volatile anesthetics produce dose-dependent reductions in tidal volume and minute ventilation, cause tachypnea, and blunt ventilatory response to hypercapnia and hypoxia.
- During anesthesia with volatile agents, diaphragmatic function remains relatively well preserved, whereas inspiratory rib cage muscles are significantly depressed resulting in insufficiency of breathing or paradoxical breathing.
- Volatile anesthetics can compromise upper airway patency. Even at low concentrations, upper airway obstruction can occur in susceptible patients, including elderly, obese, or critically ill patients.
- Volatile anesthetics vary in their ability to irritate airways and augment defensive airway reflexes. Sevoflurane causes the least amount of subjective airway irritation and is the anesthetic of choice for inhaled induction of anesthesia in infants and children.
- Preclinical and clinical evidence suggests therapeutic potential of isoflurane and sevoflurane in acute lung injury.
- Although concerns have been recently raised regarding the use of nitrous oxide, a lack of strong evidence does not justify abandoning it from clinical practice, especially considering its favorable cost-effectiveness.
- Xenon produces a fast on and off action and is a promising alternative for sedation in the critical care setting.

Introduction

Pulmonary pharmacology of inhaled anesthetics is complex. This chapter focuses in depth on pulmonary pharmacology of isoflurane, sevoflurane, desflurane, nitrous oxide, and xenon. The older anesthetics (including halothane, enflurane, and ether) are no longer in use in the developed countries, and are discussed here only for comparison. The lungs are unique in their exposure to a wide variety of physical forces including ventilation, blood flow, and surface tension as well as derangements of function caused by disease and environmental factors. The effects of inhaled anesthetics on ventilatory control, airway tone, mucociliary function, surfactant production, pulmonary vascular resistance (PVR), and acute lung injury (ALI) are examined in detail in this chapter.

The physical properties of commonly used inhalational anesthetics and clinical concerns are presented in Table 21.1.

Inhaled Anesthetics

ASTHMA AND BRONCHOSPASM OVERVIEW

Asthma is a chronic airway disease with an estimated worldwide annual death rate of 250,000. Asymptomatic asthma patients have relatively infrequent perioperative respiratory complications; however, bronchospasm

TABLE 21.1 The Physical Properties of Commonly Used Inhalational Anesthetics and Their Clinical Concerns

Property	Halothane	Isoflurane	Sevoflurane	Desflurane	Nitrous oxide	Xenon
Boiling point (°C)	50.2	49	59	24	–88	−108
Vapor pressure (mm Hg) at 20°C	241	238	157	669	38,770	–
Blood:gas partition coefficient	2.5	1.46	0.65	0.42	0.46	0.115
Oil:gas partition coefficient	224	91	47	19	1.4	1.9
Minimal alveolar concentration (MAC)	0.74	1.17	1.8	6.6	104	63-71
Metabolized in the body (%)	25	0.2	2-4	0.02	0	0
Clinical concerns	Hepatotoxicity		Compound A	Airway irritation	Gas expansion	Apnea

develops in about 9% of asthmatics in the perioperative period.[1] Twenty-five percent of asthmatics may present with wheezing after induction of anesthesia,[2] and 1.7% of asthma patients sustain a poor respiratory outcome.[3] In addition, acute bronchospasm can occur at induction, intubation, or during maintenance of anesthesia without prior history of asthma or COPD. According to the ASA Closed Claims Project[4] 40 cases of bronchospasm resulted in settled malpractice claims, with 88% involving brain damage or death. Importantly, only half of the patients had preexisting asthma or COPD. Adverse respiratory events accounted for 28% of claims related to anesthesia-related brain damage and death in the United States; they were associated with the highest mean cost per closed claim. In France, 7% of anesthesia-related deaths were also attributed to bronchospasm.[5] A nonallergic mechanism was involved in nearly 80% of cases. Although bronchospasm caused by airway irritation occurred more frequently in patients who had one or more predisposing factors including asthma, heavy tobacco smoking, or bronchitis, only 50% and 60% of patients with nonallergic and allergic bronchospasm, respectively, had history of asthma.

PHYSIOLOGY OF BRONCHIAL SMOOTH MUSCLE

Airway resistance is increased, at least in part, by an increase in bronchiolar smooth muscle (BSM) tone. BSM extends down to the terminal bronchioles and is controlled primarily by autonomic nervous system activity. Nonadrenergic, noncholinergic mechanisms, activated by the stimulation of the afferent bronchopulmonary sensory C fibers, play a role in BSM constriction to tachykinins, vasoactive intestinal peptide (VIP), adenosine, and calcitonin gene-related peptides.

Asthmatic bronchiolar constriction involves complex interactions of airway nerves, smooth muscle, epithelium, and inflammatory cells. In contrast, reflex bronchoconstriction caused by airway irritation is mediated by sensory afferents in the nucleus of the solitary tract (NTS), projecting to vagal preganglionic neurons (VPN). Glutamate modulates stimulation of NTS and VPN, whereas γ aminobutyric acid (GABA) is inhibitory from NTS projecting to VPN. VPN projections to the airways release acetylcholine (ACh) predominantly onto M3 receptors, inducing bronchoconstriction. Baseline airway tone is also mediated by the vagus nerve. The muscarinic acetylcholine receptors (mAChRs, M1-M5) on BSM are G protein-coupled receptors, three of which (M1, M2, and M3) are expressed in the lungs of humans and of most mammals.[6] Belmonte and colleagues[7] reviewed the essentials of muscarinic control of mAChRs in the lungs. Neuronal inhibitory M2 muscarinic ACh receptors on parasympathetic nerves are responsible for limiting ACh release from these nerves (Fig. 21.1).

ROLE OF CALCIUM

Alterations in cytoplasmic ionized calcium concentration (ICa^{+2}) and calcium (Ca^{+2}) influx result from the interplay of cyclic nucleotides in BSM that alters myosin light chain (MLC) and MLC kinase activity. Ca^{+2}/calmodulin-dependent MLC kinase is critical for tonic smooth muscle contraction.[8] Agonist activation of BSM also involves a second messenger, cADP ribose, resulting in inositol triphosphate (IP_3)-mediated release of Ca^{+2} from sarcoplasmic reticulum via activated ryanodine channels.[9] This release is followed by an increase in sodium (Na^+) influx across the cell membrane. This localized increase in Na^+ may switch the Na^+/Ca^{2+} exchanger into reverse mode, leading to even more Ca^{2+} influx and greater bronchial constriction. Several different cyclic adenosine monophosphate (cAMP) signaling compartments exist in airway smooth muscle that are responsive to different hormones and neurotransmitters.[10] The mechanical stretch of human BSM cells also causes contraction via an influx of Ca^{2+} through unique stretch-activated nonselective cation channels.[11] Adenosine indirectly enhances contraction of airway smooth muscle via the activation of mast cells and via nerves by directly stimulating adenosine type I receptors on airway smooth muscle, thereby rapidly mobilizing ICa^{2+} stores through G proteins and IP_3 signaling. Agonist-induced stimulation of *particulate* guanylyl cyclase relaxes bronchial smooth muscle by attenuating inward Ca^{2+} current, whereas stimulation of *soluble* guanylyl cyclase by substances such as nitric oxide (NO) reduces ICa^{2+} concentration and Ca^{2+} sensitivity.[12]

HISTAMINE

Release of histamine in the airway produces reflex bronchoconstriction from actions on H1 receptors on BSM, eliciting activation of phospholipase C and protein kinase C (PKC) downstream mediators, leading to release of Ca^{2+} from intracellular stores. This leads to calcium ion entry through calcium channels, cation channels of the transient receptor potential (TRP1) channel type, and stimulation of a Na^+/

Fig. 21.1 Muscarinic acetylcholine receptors *(mAChRs)* on pulmonary parasympathetic nerves (PSN) and airway smooth muscle (ASM). Acetylcholine (ACh) released by PSN stimulates M2 mAChRs on ASM resulting in contraction. M2 mAChRs on ASM facilitate M3 mAChR-mediated contraction by counteracting the cyclic adenosine monophosphate relaxant pathway. Release of ACh by nerves is tightly controlled by M2 mAChRs found on PSN endings. M1 mAChRs found within parasympathetic ganglia are thought to facilitate cholinergic neurotransmission that is mediated primarily by nicotinic Ach receptors.[7] (Redrawn from Belmonte KE. Cholinergic pathways in the lungs and anticholinergic therapy for chronic obstructive pulmonary disease. *Proc Am Thorac Soc.* 2005;2(4):297–304. Used with permission.)

Ca^{2+} exchanger. Nicotinic acid adenine dinucleotide phosphate has also been suggested as a potential second messenger in histamine-induced Ca^{2+} release from lysosome-like acidic compartments, functionally coupled to the endoplasmic reticulum via H1 receptor in endothelial cells.[13] This increase in bronchomotor tone is attenuated by the cholinergic antagonist atropine. The histamine-degrading enzyme, histamine N-methyltransferase, has been localized to human airway epithelium and may play a protective role against histamine-mediated bronchoconstriction.[14] Histamine-induced bronchoconstriction, measured as altered pulmonary resistance (RL) and dynamic pulmonary compliance (C_{dyn}) in response to intravenous (IV) histamine was studied in dogs to determine the bronchodilatory effects of halothane, sevoflurane, isoflurane, and enflurane. All the volatile anesthetics demonstrated an inhibitory effect on increases in RL and decreases in C_{dyn} caused by histamine.[15]

ADRENERGIC RECEPTORS

Adrenergic receptors in BSM are classified into α and β_2 types. The α2 agonists clonidine and dexmedetomidine have been shown to produce bronchodilation in central airways,[16] which may be mediated through α2 central vagolytic effects. Clinically, the β_2-receptor subtypes play an important role in BSM responsiveness. Stimulation of β_2 adrenoceptors causes cAMP-mediated relaxation via activation of protein kinase A and subsequent Ca^{2+} efflux out of the cell and into the SR. Interestingly, asthma, as well as allergy- and methacholine-induced bronchospasm, do not appear to be genetically linked to a dominant β_2-adrenoceptor gene.[17]

Respiratory epithelium releases substances that modulate BSM tone. Removal of the epithelium enhances contractile responses to ACh, histamine, or serotonin in large airways and decreases relaxation responses to isoproterenol in small airways. These responses are similar to the effect of endothelial damage on vascular smooth muscle tone. Notably, cardiopulmonary bypass does significantly affect porcine bronchiolar epithelium-mediated bronchomotor activity, in contrast to vascular endothelium-mediated smooth muscle dysfunction.[18] While endogenous epithelial factors have been identified, endogenous NO produced in respiratory epithelium likely plays a bronchodilatory role similar to that of vascular endothelium. Endothelin-1 is a potent constrictor of vascular smooth muscle and BSM that activates the IP_3 pathway and produces greater pulmonary effects compared to the systemic circulation.[19] Clinically, evaluation of the effects of the inhalational agents may be framed against a background of the major physiologic mechanisms governing normal and pathophysiologic BSM activity. These include airway disease (asthma and COPD), the overarching complex chemistry of calcium release as the BSM stimulus-contraction coupler, intrinsic factors (afferent and efferent ACh signaling, α2 receptor signaling, NO and endothelin-1, allergy and histamine release), and extrinsic factors (physical and chemical irritants, e.g., endotracheal tubes), capable of promoting reflex bronchoconstriction.

Effects of Inhaled Anesthetics

In general, all volatile anesthetics are bronchodilators, making them a good choice for patients with increased airway resistance. Using computed tomography (CT), Brown and colleagues demonstrated that halothane causes dose-dependent bronchodilation in a dog (Fig. 21.2).[20]

Eliminating indirect effects of arterial carbon dioxide (CO_2) tension is important when examining the actions of volatile anesthetics on bronchial tone, especially during spontaneous ventilation. This is because hypercapnia-induced bronchodilation and hypocapnia-induced bronchoconstriction are both attenuated by isoflurane.[21] Thus a concentration-dependent bronchodilator effect

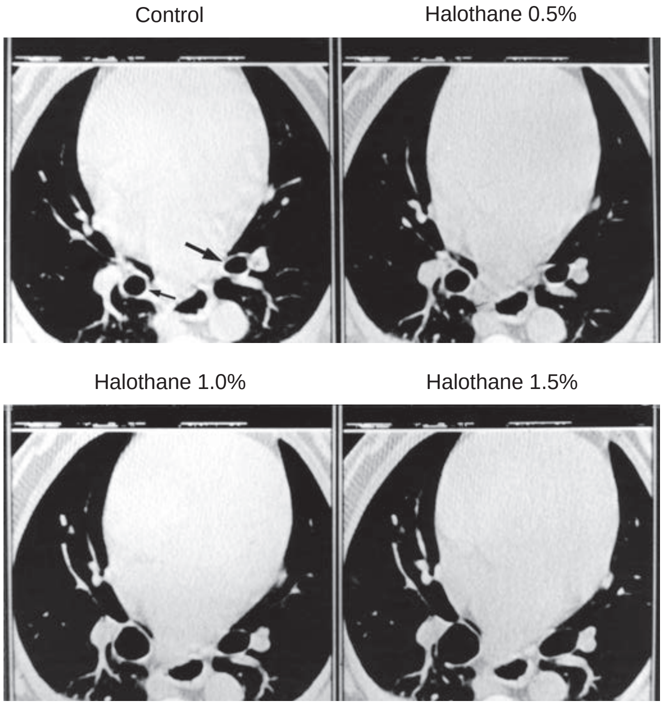

Fig. 21.2 High-resolution computed tomography scans from one dog. *Upper left:* Control. *Upper right:* During 0.5% halothane. *Lower left:* During 1.0% halothane. *Lower right:* During 1.5% halothane. of volatile anesthetics may be indirectly attributable to increase in CO_2 tension. The structure of the respiratory epithelium changes from pseudostratified columnar cells of the large airways to thinner, cuboidal cells of the bronchioles, and thus a relatively large amount of histologic heterogeneity exists between these regions. The specific effects of volatile anesthetics on the bronchioles depend on the location in and the structure of the respiratory tree. In vitro, isoflurane preferentially relaxes the bronchioles rather than the bronchi.[22] Isoflurane and halothane dilate fourth order bronchi at equivalent minimum alveolar concentration (MAC) values.[23] Similarly, at up to 1 MAC, isoflurane, sevoflurane, and desflurane attenuate methacholine-induced bronchoconstriction in open-chest, pentobarbital-anesthetized rats.[24] Isoflurane and sevoflurane also appear to have greater inhibitory effects on bronchial contraction as compared with tracheal smooth muscle contraction.[25] Furthermore, halothane, desflurane, and isoflurane relax distal airways (e.g., bronchioles) to a greater extent than proximal airways (e.g., bronchi).[26] These differential effects appear to be related to the type of voltage-dependent Ca^{2+} (VDC) channels that are present in these regions.

Inhalation of 1 or 2 MAC halothane, enflurane, sevoflurane, and isoflurane did not alter baseline pulmonary resistance and dynamic pulmonary compliance, but these anesthetics significantly attenuated increases in airway resistance and decreases in dynamic respiratory compliance in response to intravenous histamine. Halothane was the most effective bronchodilator, whereas responses to isoflurane, enflurane, and sevoflurane were similar.[15] In an isolated lung model, desflurane produced bronchodilation at 1 MAC but increased airway resistance at 2 MAC,[27] presumably resulting in part from significant increases in inspired gas density at higher MAC. Isoflurane, sevoflurane, and desflurane at 1.0, 1.5, and 2.0 MAC in 25% O_2 were all examined in a two-chamber test lung model with fixed resistance. All anesthetics demonstrated increased density and calculated resistance at higher MAC, with desflurane producing the highest increase in resistance at 2.0 MAC.[28] In a randomized clinical trial evaluating the same agents at 1.0 and 1.5 MAC, total inspiratory resistance (R[rs]), minimal resistance (R[min]), and effective resistance (D[Rrs]) were calculated using the end-inspiratory occlusion technique. No significant differences of those parameters were observed during administration of the three agents at 1 MAC for 30 min. At 1.5 MAC, desflurane caused a maximum increase in R(rs) by 26% and in R(min) by 30% above baseline, in contrast to isoflurane and sevoflurane, which did not have a significant effect on R(rs) and R(min).[29] Presumably, this increased resistance is due at least in part to the greater net viscosity of the higher absolute concentration of desflurane at 1.5 MAC. Other factors may also cause the reduction in the bronchodilation of desflurane at higher concentrations, especially in smokers.[30] Halothane, enflurane, and sevoflurane are equivalent at dilating third- or fourth-generation bronchi as directly measured with a fiberoptic bronchoscope in vivo.[31]

It appears that desflurane can both augment or inhibit bronchoconstriction (see below). At 1 MAC desflurane and sevoflurane blocked, to a similar degree, the increase in central airway resistance after a cholinergic challenge in rabbits. Both anesthetics reduced basal bronchial tone by 30% to 40%. This effect was consistently observed in the presence or absence of allergic airway inflammation and bronchial hyperresponsiveness.[32] When the mechanism of constriction is centrally mediated, such as with a cholinergic challenge,[22,24,33,34] desflurane appears to play a beneficial role in attenuating bronchoconstriction. However, when the mechanism of airway constriction is due to nonadrenergic, noncholinergic activation with tachykinins, desflurane may augment and worsen constriction.[35,36] Thus clinicians tend to avoid using desflurane in patients with reactive airway disease.

EFFECTS OF INHALED ANESTHETICS ON BRONCHOMOTOR TONE IN HUMANS AND THE WORK OF BREATHING

Sevoflurane (1 MAC) reduced respiratory system resistance by 15% in patients undergoing elective surgery, whereas desflurane had no effect.[30] Rooke and associates[37] compared the bronchodilating effects of halothane, isoflurane, sevoflurane, desflurane, and thiopental–nitrous oxide in healthy patients undergoing induction of anesthesia and tracheal intubation. In contrast to thiopental–nitrous oxide, all volatile agents with the exception of desflurane significantly reduced respiratory resistance (Fig. 21.3).

The work of breathing is defined as pressure or force multiplied by the tidal volume during inspiration. Respiratory work is further divided into elastic work (required to overcome the recoil of the lung) and resistive work (required

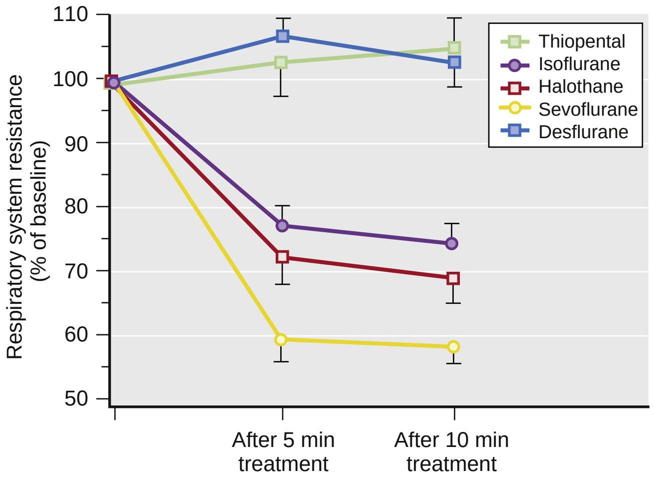

Fig. 21.3 Percent change in respiratory system resistance in patients after 5 and 10 minutes of maintenance anesthesia with either 0.25 mg/kg/min thiopental plus 50% nitrous oxide or 1.1 minimum alveolar concentration (MAC) sevoflurane, halothane, or isoflurane, or approximately 1 MAC desflurane. All volatile anesthetics except desflurane decreased resistance. Sevoflurane decreased resistance more than isoflurane. (Modified from Rooke GA, Choi JH, Bishop MJ. to overcome airway flow resistance and viscoelastic resistance of pulmonary tissues). The work of breathing is usually derived from transpulmonary pressure volume curves. Volatile anesthetics increase the work of breathing in adults and children. In rats, sevoflurane reduced pulmonary compliance at the lung periphery rather than at the airway level, thereby increasing viscoelastic and elastic pressures in the lung.[38] In addition, in a murine model of chronic asthma, sevoflurane significantly decreased resistance in central and distal airways and also lowered resistance in the lung periphery. These data suggest that sevoflurane exerts a beneficial effect in the presence of chronic airway obstruction and indicate that sevoflurane might reduce the work of breathing in comparison to other drugs (Fig. 21.4).[39]

Studies in humans demonstrate a ceiling effect where low concentrations of volatile anesthetics significantly reduce *upper airway resistance*, reflecting changes in airway smooth muscle tone in the major airways. In contrast, distal airways and lung parenchyma lack a smooth muscle component (with *lower airway and alveolar resistance* being more a measure of viscoelastic changes in the lung). Increasing concentrations of inhalational agents have diminished effect on these more distal pulmonary components and thus do not further reduce total lung resistance (Fig. 21.5).[40]

Expiration is passively affected by the recoil characteristics of the lung during normal breathing. In anesthetized patients, the ventilatory response to expiratory resistance is reduced to a greater extent than the response to inspiratory resistance. Conscious and anesthetized humans exhibit decreases in respiratory rate when expiratory resistive loads are applied, but only anesthetized subjects develop rib cage–abdominal wall motion dyssynchrony that causes less effective ventilation and reduction in minute alveolar ventilation. This concept may be particularly important in spontaneously breathing anesthetized patients who demonstrate expiratory obstruction, such as in cases of asthma, COPD, airway secretions, or during hypopharyngeal obstruction or partial breathing circuit occlusion.

Experimental studies demonstrating the equal potency of sevoflurane and isoflurane and the higher potency of halothane for bronchodilation must be extrapolated with caution because histamine-mediated experimental bronchospasm may not closely mimic tracheal intubation–induced bronchospasm in humans. Indeed, Arakawa and colleagues[41] showed that similar inspired concentrations of halothane, isoflurane, and sevoflurane produced nearly identical reductions in airway resistance in a patient with status asthmaticus. Volatile anesthetics may thus be an effective therapeutic modality in status asthmaticus when conventional therapy has failed.[42,43]

β-Adrenoceptor agonists may be beneficial for treating acute bronchospasm in patients anesthetized with halothane,[44,45] but their use may not be beneficial with other volatile anesthetics. For example, the β_2-adrenergic agonist fenoterol reduced respiratory system resistance after endotracheal intubation but did not further decrease resistance when administered in the presence of 1.3% isoflurane.[46] These findings should be interpreted with caution because the technique used to determine respiratory system resistance incorporates alterations in lung and chest wall resistance, as well as tissue viscosity. The most important functional change that occurs in the presence of lung disease is increased resistance. Resistance to airflow is

typically thought of as being determined by the flow rate and airway smooth muscle tension. However, nonmuscle elements, such as lung inflammation, airway thickening, altered lung volumes, lung recoil, airway wall remodeling, mucous hypersecretion, and loss of lung elastance, also play a clinically significant role in the amount of airway narrowing. The role of volatile anesthetics in altering many of these non–smooth-muscle elements responsible for airway resistance needs further elucidation.

The effects of volatile anesthetics on bronchomotor tone are also dependent on the substance used to produce contraction in vitro.[47] Relaxation of tracheal smooth muscle by halothane and isoflurane is greatest in the presence of the endogenous mediator serotonin (resulting from anaphylactoid or immunologic reactions) compared with ACh (representing the neutrally derived mediator of reflex bronchospasm). Thus inhaled anesthetics may remain effective bronchodilators, even in the presence of severe serotonin- or histamine-induced bronchospasm that is refractory to β_2-adrenoceptor therapy. It is important to note that in anesthetized patients, volatile anesthetic–induced decreases in bronchomotor tone and neurally mediated airway reflexes may be partially opposed by a simultaneous reduction in functional residual capacity (FRC). The well-known increased risk for morbidity and mortality in patients with asthma may be at least partially attributed to these FRC-mediated increases in airway resistance. Low temperature abolished the inhibitory effects of volatile anesthetics on carbachol-induced contraction of airway smooth muscle in dogs,[48] suggesting that intraoperative hypothermia may also attenuate volatile anesthetic–induced bronchodilation.

Bronchospasm may occur in conditions and with respiratory diseases other than asthma. For example, healthy patients undergoing surgical stimulation of lung parenchyma or airways including tracheal stimulation by an endotracheal tube are at risk of developing bronchospasm. Preoperative medications, sedatives, neuromuscular blockers, and volatile anesthetics are all important factors that may trigger or attenuate bronchospasms. Regardless of the airway sensitivity prior to induction, the different pathways involved in an individual patient may yield different responses to the volatile anesthetics. Iwasaki and colleagues[49] demonstrated that sevoflurane-induced relaxation of airway smooth muscle and VDC channels were dependent on the type of hyperreactive airway model. Sevoflurane had smaller effects in a model of chronic tobacco smoking (enlarged alveolar ducts and less muscarinic hyperreactivity), compared with an antigen-acute asthmatic (ovalbumin-sensitized) model. The morphologic changes in the peripheral airway may be responsible to some degree for a decrease in the efficacy of volatile anesthetics as bronchodilators in tobacco smokers, but sevoflurane and isoflurane still decrease respiratory system resistance in patients with COPD.[50]

In children undergoing elective imaging studies, sevoflurane produced progressive reductions in the cross-sectional area of upper airway, resulting in pharyngeal airway collapse[51] (also see Chapter 93). As observed with isoflurane in animal models, the effects of sevoflurane were not uniformly distributed along the upper airway. In healthy children, sevoflurane slightly decreased airway resistance, but desflurane had the opposite effect, presumably via reduced airway size.[52]

Children with documented airway susceptibility, such as those with asthma or a recent upper respiratory tract infection, exhibit significant increases in airway resistance. In these pediatric patients, desflurane should be avoided.

MECHANISMS OF ACTION OF VOLATILE ANESTHETICS

Volatile anesthetics attenuate airway smooth muscle tone by reducing smooth muscle contractility. This action is the result of the direct effects on bronchial epithelium and airway smooth muscle cells, combined with the indirect inhibition of reflex neural pathways. Several intracellular mediators responsible for Ca^{2+} mobilization are potential sites for the action for volatile anesthetics. Inhibition of cell membrane-associated VDC channels reduces Ca^{2+} entry into the cytosol.[53] Volatile anesthetic–induced increases in cAMP concentrations cause decreases in intracellular-free Ca^{2+} by stimulating Ca^{2+} efflux and increasing Ca^{2+} uptake into the sarcoplasmic reticular (SR). In addition, a decrease in Ca^{2+} sensitivity attributable to inhibition of PKC activity, inhibition of G-protein function, and attenuation of Rho/Rho-kinase signaling pathways also play important roles.[53,54] Volatile anesthetics may also alter pulmonary resistance by affecting the density of the gas mixture.[28] In an experimental lung model of fixed pulmonary resistance, high concentrations of volatile anesthetics increased the density of the gas mixture and the calculated resistance, with desflurane producing the largest increase (Fig. 21.6).[28] Such an effect is particularly profound for ^{55}xenon which has a molecular weight of 131.2 Daltons, making it four times as dense as room air.[55]

The effects of volatile anesthetics on proximal, compared with distal, airways may be related to the differential effects on VDC channels and the relative distribution of these channels. Long-lasting (L-type) VDC channels appear to be the predominant mechanism for Ca^{2+} entry in tracheal smooth muscle, whereas both transient (T-type) and L-type VDC channels are present in bronchial smooth muscle.[25,56] Isoflurane and sevoflurane inhibit both types of VDC channels in a dose-dependent fashion, and their effects on T-type VDC channels in bronchial smooth muscle are even more pronounced (Fig. 21.7).[25]

The differential effects of volatile anesthetics on tracheal smooth muscle, compared with bronchial smooth muscle, may also be related to actions on Ca^{2+}-activated chloride channel activity[57,58] or differential sensitivities of K^+ channel subtypes.[57]

The proposed signaling pathways underlying volatile anesthetic–induced bronchodilation are depicted in Fig. 21.8.[59,60]

Volatile anesthetic–induced reductions in ICa^{2+} result from the inhibition of both VDC and receptor-gated Ca^{2+} channels. In addition, volatile anesthetics deplete Ca^{2+} stores in SR by increasing Ca^{2+} leakage. Ca^{2+} influx occurring in response to depleted SR Ca^{2+} stores is known as store-operated Ca^{2+} entry (SOCE). By depleting Ca^{2+} stores in SR, volatile anesthetics may be expected to enhance SOCE. Nevertheless, at clinically relevant concentrations, volatile anesthetics (isoflurane more than sevoflurane) also inhibit SOCE in airway smooth muscle to further reduce available Ca^{2+}.[61]

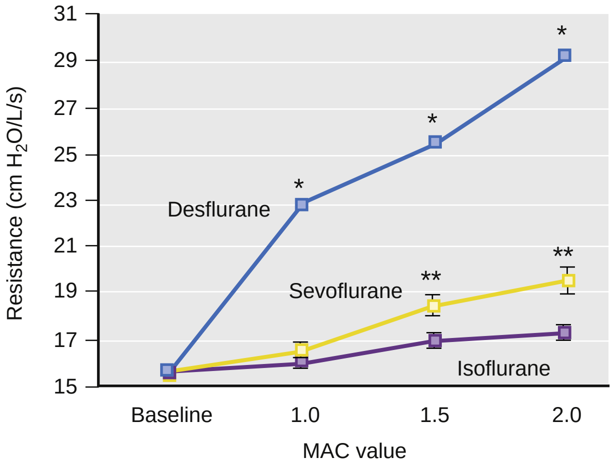

Fig. 21.6 Comparison of the effect of different volatile anesthetics at equivalent concentrations on total pulmonary resistance. At 1 minimum alveolar concentration (MAC), only desflurane significantly increased pulmonary resistance, compared with isoflurane and sevoflurane. At 1.5 and 2 MAC, sevoflurane significantly increased total pulmonary resistance compared with isoflurane, whereas desflurane caused a more pronounced increase than the other two agents. *Increased pulmonary resistance in comparison with sevoflurane and isoflurane; **increased pulmonary resistance in comparison with isoflurane. (Reproduced from Nyktari VG, Papaioannou AA, Prinianakis G, et al. Effect of the physical properties of isoflurane, sevoflurane, and desflurane on pulmonary resistance in a laboratory lung model. *Anesthesiology*. 2006;104:1202. Used with permission.)

Volatile anesthetic–induced reductions in SR Ca^{2+} appear to occur through enhancement of IP_3[62] and ryanodine-receptor channel activities.[59] Kai and coworkers[53] demonstrated that halothane attenuates ACh-induced Ca^{2+} sensitization in canine tracheal smooth muscle to a greater extent than does sevoflurane, whereas isoflurane has effect at concentrations equivalent to 2 MAC. This effect appears to be mediated, at least in part, by an increase in smooth muscle protein phosphatase,[60] modulation of G proteins (specifically G_q and G_I that exert actions on cyclic guanosine monophosphate [cGMP]),[53] or modulation of the Rho/Rho-kinase signaling pathways.[63,64] Volatile anesthetics interact with the muscarinic receptor–heterotrimeric G protein complex to prevent agonist-promoted nucleotide exchange at the $G\alpha$ subunit of the G protein.[65,66] Halothane, sevoflurane, and, minimally, isoflurane exert direct effects on muscarinic receptor–mediated contraction of isolated airway smooth muscle.[67] The inhibitory effects of volatile agents on the biochemical coupling between the M_3 muscarinic receptor and the $G\alpha_q$ heterotrimeric G protein is completely reversible with time. Isoflurane-induced relaxation of precontracted bronchial smooth muscles is significantly augmented by pretreatment with a Rho-kinase inhibitor, whereas sevoflurane-inhibited guanosine-5′-triphosphate (GTP) γ S-stimulated contraction and membrane translocation of both Rho and Rho-kinase in a concentration-dependent manner. These latter actions play important roles in Ca^{2+} sensitization.[54] The final pathway in airway smooth muscle contraction is the generation of force and shortening of smooth muscles regulated by myosin cross-bridge number and kinetics. Isoflurane modulates both cross-bridge number and cycling rates of isolated rat airway smooth muscle.[67]

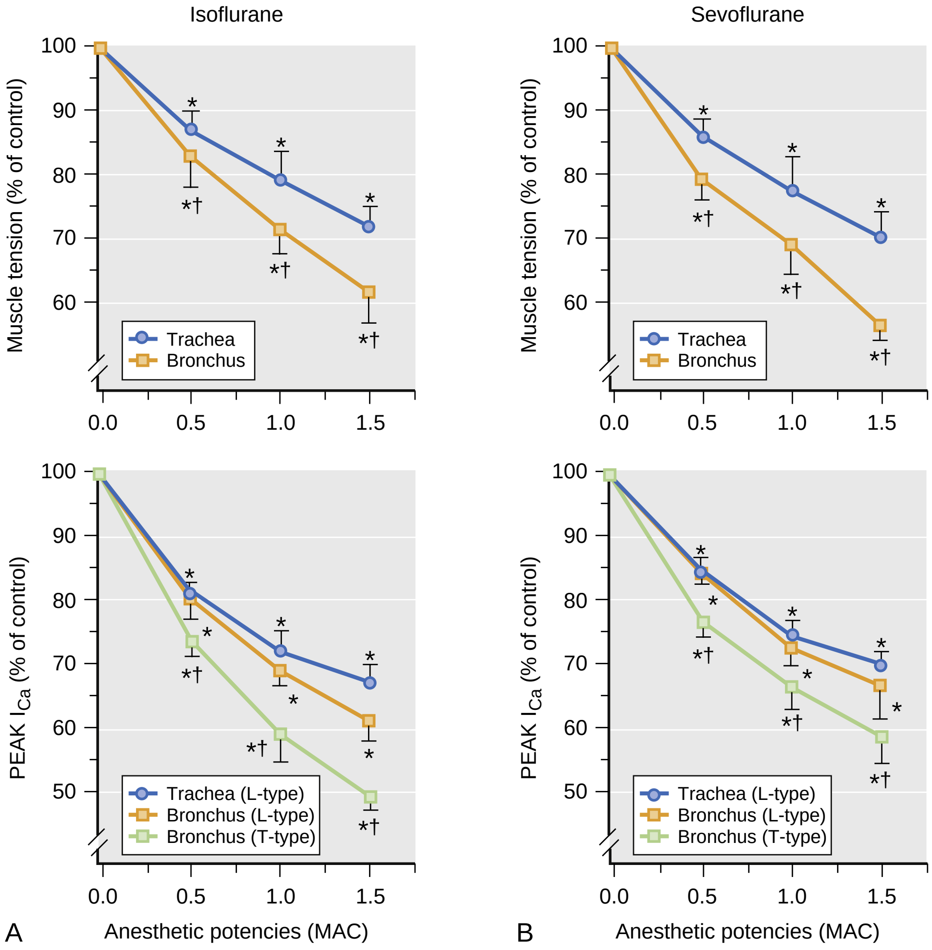

Fig. 21.7 Effect of isoflurane and sevoflurane on porcine tracheal versus bronchial smooth muscle tension or inward calcium (Ca^{2+}) current intercellular calcium (ICa^{2+}) through T- and L-type voltage-dependent Ca^{2+} (VDC) channels. No differences were observed in the inhibition of L-type VDC channels. Both anesthetics had greater inhibitory effects on T-type VDC channels in bronchial smooth muscle. Different inhibitory effects of volatile anesthetics on T- and L-type voltage dependent Ca^{2+} channels in porcine tracheal and bronchial smooth muscles. *Anesthesiology*. 2001;94:683. Used with permission.)

The bronchodilatory effect of volatile anesthetics is also mediated by GABA A (GABA$_A$) receptors in the brainstem or GABA B (GABA$_B$) receptors on preganglionic cholinergic nerves in the lung similar to the observations with propofol.[68] Indeed, GABA$_A$ and GABA$_B$ receptors, as well as glutamic decarboxylase (enzyme responsible for GABA synthesis), are located in airway epithelial and smooth muscle cells. GABA levels increase and localize to airway smooth muscle after contractile stimuli in upper airways. Furthermore, a GABA agonist reversed augmentation of cholinergic-induced tracheal ring contraction.[68,69]

Inhaled but not intravenous halothane attenuated bronchoconstricting effects of low inhaled concentrations of CO$_2$ in rat distal bronchi, suggesting that halothane exerts a direct action on airway muscle tone or local neural reflex arcs rather than centrally controlled reflex pathways. Consistent with this hypothesis, halothane-, isoflurane-, sevoflurane-, and desflurane-induced dilation of distal bronchial segments is partially dependent on the presence of bronchial epithelium.[23,70] Prostanoids (e.g., prostaglandin E$_2$ or I$_2$) or NO may be responsible for the bronchodilatory effects of volatile anesthetics under these conditions. Focal epithelial damage or inflammation may occur in small airways in patients with asthma or allergen exposure, resulting in a reduced bronchodilatory response to volatile anesthetics.[71] Nevertheless, the most pronounced bronchodilatory action of volatile anesthetics in patients with chronic reactive airway disease occurs primarily in the proximal rather than distal airways.

Direct stimulation of intrinsic airway nerves in vitro produces a contractile response that is inhibited by atropine. Volatile anesthetic–induced bronchodilation also occurs by modulation of this airway cholinergic neural transmission mediated through prejunctional and postjunctional mechanisms.[72,73] The combination of atropine and halothane did not increase airway caliber over that attained with either drug alone, suggesting that halothane dilates airways by blocking vagal tone during unstimulated conditions.[74] Potent tracheal constriction also occurs in response to the endogenously produced endothelin-1. Isoflurane attenuated the endothelin-1–induced airway smooth muscle contraction in rat tracheal rings, suggesting another potential mechanism for airway smooth muscle relaxation.[75]

Mucociliary Function and Surfactant

NORMAL MUCOCILIARY FUNCTION

The upward clearance of mucus from the tracheobronchial tree is responsible for removal of foreign particulate matter, microorganisms, and dead cells and is a primary pulmonary defense mechanism. Although ciliated respiratory epithelium cells are present throughout the respiratory tree, the density of ciliated respiratory epithelium progressively decreases from the trachea to the terminal bronchioles. Cilia are hair-like appendages, consisting of hundreds of proteins organized around a microtubular architecture. They are anchored to the apical cytoplasm by a basal body and extend from the cell surface into the extracellular space.[76,77] Cilia are classified as either motile or immotile (primary). Motile cilia were thought to be responsible for generating extracellular fluid movement or propelling individual cells, whereas primary cilia were believed to be vestigial. However, primary cilia are important environmental sensors. In human bronchial epithelium, they play a key role in sensing and transducing extracellular mechanochemical signals and are also capable of identifying smooth muscle injury.[78] Indeed, ciliopathies are responsible for a variety of pediatric disorders such as primary ciliary dyskinesia and autosomal recessive polycystic kidney disease.[76,79] Christopher et al. studied the effects of temperature (15°C-37°C) with varying combinations with fentanyl, dexmedetomidine, and isoflurane on the cilia of mouse tracheal epithelia. There was a linear correlation between cilia motility and temperature. Fentanyl exerted stimulatory effects on cilia, while dexmedetomidine and isoflurane both inhibited cilia function. When added together, fentanyl, dexmedetomidine, and isoflurane were all cilia inhibitory. In contrast, fentanyl plus dexmedetomidine did not significantly alter ciliary function, with results suggesting complex drug-drug and drug-temperature interactions not predicted by simple summation of effects.[80]

Ciliary motion consists of a rapid stroke in a cephalad direction, followed by a slower caudal recovery stroke. Movements of cilia are closely coordinated to move matter efficiently toward the trachea in a wave motion known as *metachronism*. Each motile cilium is organized in nine peripheral microtubule pairs surrounding a central pair (9+2). During a beat, dynein arms undergo an adenosine triphosphate (ATP)–dependent attachment, retraction, and release cycle with the adjacent doublet, which results in a sliding motion. The basal bodies of the motile cilia are anchored to the microtubules, nexin links, and radial spokes and are further restricted by the ciliary membrane. This anatomic constraint converts the sliding motion into a bend.

The quantity and physical properties of the mucous layer may also promote the coordination of ciliary beats. Mucus is a mixture of water, electrolytes, and macromolecules (e.g., lipids, mucins, enzymes) secreted by goblet cells and mucosal glands. Thicker layers of mucus slow the removal of surface particles from the airway, whereas low-viscosity mucus promotes more rapid ciliary transport. Impaired mucociliary function in the upper airways correlates with low levels of nasal NO, although the clinical significance of this finding is unclear.[81] Direct nervous system control of ciliary coordination has not been demonstrated in vertebrates, but mucociliary clearance is closely related to autonomic nervous system activity, most likely related to changes in physical characteristics of respiratory secretions (also see Chapter 103).[82]

Several factors affect mucociliary function in mechanically ventilated patients contributing to lung atelectasis and hypoxemia. For example, insufficiently humidified inspired gases reduce ciliary movement and desiccate mucus. In dogs, the flow rate of tracheal mucous was maintained within the basal range during a 40-minute exposure to inspired dry air at a temperature higher than 32°C. However, 3 hours of inhalation of dry air caused a complete cessation of the flow of tracheal mucus, which was restored by the subsequent use of inspired gases with 100% relative humidity at 38°C. Several anesthesia-related factors also reduce the rate of mucous movement, including high-inspired oxygen (O_2) concentrations, adjuvant medications (e.g., corticosteroids, atropine, β-adrenoreceptor antagonists) that affect bronchial tone, the presence of an endotracheal tube, and positive-pressure ventilation.[83]

EFFECTS OF INHALED ANESTHETICS ON MUCOCILIARY FUNCTION

Volatile anesthetics and nitrous oxide diminish the rates of mucous clearance by decreasing ciliary beat frequency, disrupting metachronism, and altering the physical characteristics or quantity of mucus. In contrast to many intravenous anesthetics,[84,85] halothane, enflurane, isoflurane, and sevoflurane all reduce ciliary movement and beat frequency in vitro.[84-87] Among the volatile anesthetics, sevoflurane exhibited the weakest cilioinhibitory effects in rat cultured tracheal epithelial cells in vitro (Fig. 21.9).[87]

Gamsu and colleagues[88] measured the rate of tantalum (a powder that adheres to airway mucus) clearance from the lungs of postoperative patients who received general anesthesia for intraabdominal or lower extremity surgeries. Tantalum retention was closely correlated with the retention of mucus and shown for as long as 6 days after intraabdominal surgery. The administration of halothane (1%-2%) and nitrous oxide (60%) rapidly decreased the rate of mucous movement in females undergoing gynecologic surgery. Little or no mucous motion was observed after 90 minutes of halothane–nitrous oxide inhalation.[89] Bronchial mucosal transport velocity was also determined using radiolabeled albumin microspheres distally deposited in the mainstem bronchi using a fiberoptic bronchoscope in healthy patients. In contrast to the findings of the study with halothane, mucous velocity was unchanged during the administration of 1.5 MAC isoflurane.[90]

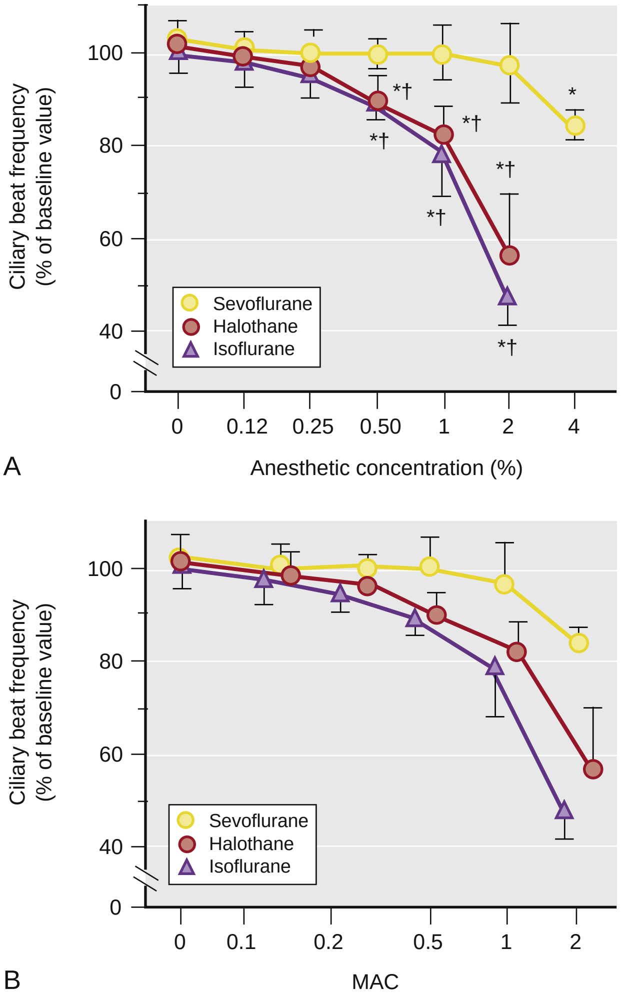

Fig. 21.9 Effects of sevoflurane, halothane, and isoflurane on ciliary beat frequency (CBF) in cultured rat tracheal epithelial cells. CBF was measured at baseline and 30 minutes after exposure to various anesthetic concentrations. Values represent mean ± standard deviation. (A) Plot of percent baseline CBF versus anesthetic concentration. $^{*}P < .05$ versus 0% vehicle. $^{\dagger}P < .05$ versus sevoflurane at the same concentration. (B) Percent baseline CBF versus minimum alveolar concentration *(MAC)*. (Modified from Matsuura S, Shirakami G, Iida H, et al. The effect of sevoflurane on ciliary motility in rat cultured tracheal epithelial cells: a comparison with isoflurane and halothane. *Anesth Analg.* 2006;102:1703. Used with permission.)

Impairment of ciliary beat frequency, mucociliary clearance, and bronchial mucous transport contribute to pulmonary complications, including retention of secretions, atelectasis, and lower respiratory tract infection. A reduction in bronchial mucous transport of as little as 3.5 mm/min (normally 10 mm/min) was associated with an increase in pulmonary complications in patients who were mechanically ventilated for 4 days in the intensive care unit (ICU).[91] Thus pulmonary therapy directed at enhancing clearance of secretions from the airways may be beneficial in the immediate postoperative period, regardless of the type of volatile anesthetic chosen.

Compared to nonsmokers, tobacco smokers have significantly slower bronchial mucous transport velocities and are prone to more frequent pulmonary complications when undergoing major abdominal or thoracic surgeries.[92] The specific effects of volatile anesthetics on mucous movement in smokers have not been well studied. However, it is likely that an additive or synergistic negative effect on mucous transport may be present. Impairment of mucociliary function also occurs after lung transplantation. The mechanism for this dysfunction may be related to alterations in the surface properties of mucus and significant impairment of mucociliary transport distal to bronchial transection and re-anastomosis.[93] The effects of volatile anesthetics on mucous transport in lung transplant patients have not been described, but the baseline reductions in mucociliary movement would certainly predispose to postoperative respiratory complications.

EFFECTS OF INHALED ANESTHETICS ON SURFACTANT

Pulmonary surfactant decreases the work of breathing by reducing surface tension at the fluid-gas interface. Surfactant is a mixture of proteins and phospholipids synthesized by alveolar type II cells. Similar to mucus, surfactant plays a role in removing foreign particles from airways while also enhancing the bactericidal actions of alveolar macrophages. Halothane[94] and isoflurane[95] produced a transient dose-dependent reduction in phosphatidylcholine (a major component of surfactant) synthesis by alveolar cells during a 4-hour exposure. High concentrations of halothane also disrupted the energy metabolism of cultured alveolar cells as indicated by reduced ATP content and enhanced glycolytic metabolism. Halothane and isoflurane potentiated a hydrogen peroxide–induced reduction of phosphatidylcholine content in alveolar type II cells[95,96] by affecting cell energetics. Halothane decreased the Na^+/K^+–adenosine triphosphatase (Na^+/K^+-ATPase), and Na^+ channel activity in alveolar type II cells, probably related to alterations in ICa^{2+} or ATP depletion. A similar decrease in type II alveolar cell Na^+/K^+-ATPase occurs after the administration of isoflurane.[97] Transepithelial Na^+ transport helps regulate alveolar fluid balance, and, as a result, impairment of this transport system may contribute to alveolar edema. This observation may be especially relevant in surgical patients because volatile anesthetics decrease alveolar epithelial fluid clearance.[98]

The phospholipid composition of surfactant is critical to its functional integrity. Another crucial component of surfactant is the hydrophobic surfactant-associated protein C synthesized by alveolar type II cells. This protein facilitates the adsorption and spreading of phospholipids to form the surfactant monolayer and enhances the lipid uptake into alveolar type II cells. Exogenous surfactants that contain surfactant-associated protein C are effective at decreasing barotrauma and mortality in vivo. Clinically relevant concentrations of halothane increase surfactant-associated protein C messenger ribonucleic acid (mRNA) in vitro but cause the opposite effect in mechanically ventilated rats.[99] Extrapolation of these findings to patients should be approached with caution, but halothane and mechanical ventilation may play a potentially additive and deleterious role on surfactant production and homeostasis of the alveolar space, particularly in the presence of ALI. In a rat model, sevoflurane produced deterioration in surfactant composition and viscosity with impaired lung mechanics promoting alveolar collapse[100]; again, caution is warranted in extrapolating these findings to humans. Bilgi and colleagues compared the effects of low-flow and high-flow inhalational anesthesia with nitrous oxide and desflurane on mucociliary activity and pulmonary function tests in humans. The forced vital capacity and forced expiratory volume and mucociliary clearance of saccharin powder were better preserved with low-flow rather than a high-flow technique, suggesting that heated and humidified gases may have a greater impact than the inhaled anesthetics themselves.[101]

Prolonged administration of volatile anesthetics may produce mucous pooling and impair alveolar cell surfactant metabolism. These actions may result in adverse effects on pulmonary function including development of atelectasis and infections. Patients with excessive or abnormal mucous or surfactant production and patients with ALI, chronic bronchitis, asthma, cystic fibrosis, and chronic mechanical ventilation are at the greatest risk. Clinical studies of the effects of volatile anesthetics on mucociliary function, surfactant metabolism, and immunomodulation in patients with compromised pulmonary function are still sparse.

PULMONARY VASCULAR RESISTANCE

Regulation of Pulmonary Vascular Tone

The pulmonary vascular bed is a low-pressure, high-flow system. Normal pulmonary arterial (PA) pressure is approximately one-fifth of the systemic arterial pressure. Correspondingly, PVR is lower than systemic vascular resistance. The main pulmonary artery and its major branches have a thinner media and less vascular smooth muscle than the aorta and major proximal arterial vessels. Changes in pulmonary vascular smooth muscle tone alter PVR by affecting the slope of pressure-flow relation. Such direct changes may be produced by a rapid rise in cytoplasmic ICa^{2+} of the pulmonary vascular smooth muscle cell or by alterations in sympathetic nervous system activity, arterial O_2 and CO_2 tension, acid-base balance, or plasma catecholamine concentrations. Hypercapnia at constant pH (i.e., isohydria) does not alter tone in isolated pulmonary arteries, but normocapnic acidosis relaxes isolated pulmonary arteries by an endothelium-independent mechanism.[102] However, pulmonary endothelial dysfunction potentiates hypercapnia-induced vasoconstriction.[103] Changes in PA pressure and PVR exert important effects on pulmonary gas or fluid exchange. An increase in PVR occurring in conjunction with a corresponding increase in PA pressure promotes interstitial fluid transudation. An acute increase in PVR can be caused by large tidal volumes, high positive end-expiratory pressure, alveolar hypoxia, hypercarbia, acidosis, and critical closing pressure. Hypoxia and acidosis have a synergistic effect increasing PVR. In contrast to acute pulmonary hypertension, the development of chronic pulmonary hypertension involves endothelial dysfunction with persistent vasoconstriction due to imbalance between endogenous vasoconstrictors (including thromboxane A_2, angiotensin 2, and endothelin 1) and vasodilators (including NO and prostacyclin), smooth muscle proliferation, platelet aggregation, vascular remodeling and thrombosis, and formation of plexiform lesions that irreversibly obliterate pulmonary arterioles. Clinically, the use of positive inotropic medications (e.g., milrinone) or expanded blood volume can passively decrease PVR by increasing cardiac output. Volatile anesthetics may also have indirect effects on PVR through a reduction in lung volumes during spontaneous ventilation. To assess the total effect of the volatile anesthesia, the volume status and mechanical ventilation on the pulmonary pressures, and right heart function, either transthoracic or transesophageal echocardiography should be considered.

Endogenously produced NO plays an important role in the regulation of PVR both in the healthy, normoxic lung and during hypoxia. NO is generated via oxidation of a terminal guanidinium nitrogen on the amino acid L-arginine. The reaction utilizes molecular O_2 and NADPH as substrates, requires the presence of tetrahydrobiopterin, flavoproteins, calmodulin, and thiols as cofactors, and yields NO in addition to the co-product L-citrullin.[104] This oxidation is catalyzed by a single enzyme protein, NO synthase (NOS), which exists in three distinct isoforms. Constitutive calcium-dependent isoforms of the enzyme were originally purified from neuronal tissue (nNOS) and vascular endothelium (eNOS).[105,106] When stimulated by bacterial endotoxin and proinflammatory cytokines, a third calcium-independent isoform (iNOS) is induced in various cell types including endothelial and vascular smooth muscle cells, macrophages, and fibroblasts. Once expressed, iNOS is independent of calcium, and NO production continues at a maximum rate. All three NOS isoforms are widely distributed in the lung, extensively involved in vascular homeostasis, and intimately linked to the pulmonary O_2 environment.[107]

NO diffuses away from its point of synthesis and interacts with various intracellular molecular sites both within the generating cells and the target cells. The best-characterized target for NO is iron, bound within certain proteins, either as a heme group or as an iron-sulfur complex. The interaction of NO with the heme component of soluble guanylate cyclase stimulates enzymatic conversion of guanosine triphosphate to cGMP.[104] In turn, increased intracellular levels of cGMP cause relaxation of systemic and pulmonary vascular and nonvascular smooth muscles by several mechanisms. Besides lowering free intracellular calcium and attenuating calcium transients, cGMP causes hyperpolarization of muscle cells through activation of potassium channels.

Inhalation of gaseous NO produces selective pulmonary vasodilation in well-ventilated lung areas and may be beneficial in the treatment of neonatal pulmonary hypertension resulting from a variety of congenital heart diseases, hypoplastic lung, and meconium aspiration. Inhaled NO has also some benefits in the treatment of acute pulmonary hypertension in adults, provided that the PVR is not fixed by remodeling and hypertrophy of pulmonary vasculature. Additionally, the use of inhaled NO to reduce PVR in pediatric and adult patients during cardiac surgeries has become common (also see Chapters 67, 94, and 104).[108]

Prostacyclin is another endogenous vasodilator produced by the endothelium that causes smooth muscle relaxation through adenylyl cyclase stimulation and production of cAMP. Prostacyclin is used in inhaled or injected formulations to produce pulmonary vasodilation in patients with chronic PA hypertension. Another group of pulmonary vasodilators, including sildenafil and tadalafil, acts by inhibiting cGMP-specific phosphodiesterase type 5 (an enzyme that is responsible for cGMP degradation) and is used for therapy of refractory PA hypertension. Finally, riociguat, a novel drug that directly stimulates soluble guanylate cyclase independently of NO, has been recently approved for treating patients with chronic pulmonary hypertension and chronic thromboembolic pulmonary hypertension.[109]

MECHANISMS OF HYPOXIC PULMONARY VASOCONSTRICTION

Changes in PVR affect the regional distribution of blood flow within the lung and produce changes in ventilation-perfusion matching and gas exchange. The distribution of PA blood flow and ventilation in the lung is mainly a gravity-dependent phenomenon that is primarily mediated by the asymmetric branching of airways and blood vessels, thereby establishing regional heterogeneity.[110] An increase in PVR occurring within an area of atelectasis optimizes gas exchange by shifting blood flow away from the atelectatic segment to well-ventilated regions of the lung. This phenomenon, termed hypoxic pulmonary vasoconstriction (HPV), is unique to the pulmonary circulation because other vascular beds (e.g., coronary and cerebral) dilate in response to hypoxia. Thus HPV maintains oxygenation, while medications (including volatile anesthetics) that interfere with HPV may adversely affect gas exchange. HPV plays an especially important role in the presence of atelectasis, pneumonia, reactive airway disease, acute respiratory distress syndrome (ARDS), or one-lung ventilation (OLV). It usually does not contribute to pulmonary blood flow heterogeneity under normal conditions in supine humans.[111]

HPV is a locally mediated phenomenon that occurs when alveolar O_2 tension falls below approximately 60 mm Hg and is maximal when O_2 tension is approximately 30 mm Hg. HPV was first identified in 1894, and the precise mechanism is only now becoming clear. Specialized O_2-sensing cells modulate respiratory and circulatory function to maintain a normal O_2 supply. Hypercapnia-induced acidosis increases PVR in intact animals and in isolated, perfused lungs. Acidosis-induced increases in PVR are relatively small at normal alveolar O_2 tensions but are dramatically enhanced during alveolar hypoxia. Local acidosis and increases in alveolar CO_2 tension augment HPV and further improve arterial oxygenation in healthy lungs. High CO_2 concentrations reduce NO levels,[112] but whether this action plays a part in hypercarbia-induced improvements in the ventilation-perfusion ratio is unclear.[113]

Although the hypoxia-mediated endothelial-derived vasoconstrictor has yet to be identified,[114] hypoxia releases Ca^{2+} from smooth muscle SR via ryanodine receptors,[115] enhances Ca^{2+} sensitization,[114-116] and modulates voltage-gated K^+ channels in smooth muscles.[117] Other mediators of the hypoxic-response coupling have been identified.[116,118]

Wang and colleagues[119] have recently demonstrated that both connexin 40-mediated retrograde endothelial signal conduction for O_2 sensing, as well as Ca^{2+} influx at TRP1 channel V4 on pulmonary arterioles[120] are required for HPV. Ultimately, there are a number of contenders for the role of HPV oxygen sensor, yet there is still no consensus on how this happens in vivo, with most of the proposed mechanisms interlinked, depending on the phase of HPV, the degree of hypoxia, involvement of anesthetic or other agents.[121]

INHALED ANESTHETICS AND HYPOXIC PULMONARY VASOCONSTRICTION

All volatile anesthetics dilate the pulmonary vascular bed. In a thorough review, Akata[122] discussed the mechanisms by which inhaled anesthetics produce this vasodilation, including a reduction in free cytosolic Ca^{2+} and inhibition of myofilament Ca^{2+} sensitivity. However, the vasodilator effect of volatile anesthetics is modest in normal lungs, and the small attenuation of PVR is usually offset by a concomitant reduction in cardiac output. The net effect of these hemodynamic changes results in minor, if any, changes in PA pressure concomitant with a small decrease in total pulmonary blood flow. In contrast to their action as direct pulmonary vasodilators, volatile anesthetics also attenuate K_{ATP} channel-mediated and endothelium-dependent pulmonary vasodilation in chronically instrumented dogs.[123-125] This inhibition of pulmonary vasodilation is not a uniform observation under all experimental conditions. For example, isoflurane and halothane, but not enflurane, enhance isoproterenol-mediated vasodilation.[126,127] Unlike the findings with other volatile anesthetics, K_{ATP} channel–mediated pulmonary vasodilation in response to a K^+ channel agonist (lemakalim) is preserved during sevoflurane anesthesia.[125] Indeed, evidence suggests that halothane, enflurane, and isoflurane, but not sevoflurane, differentially modulate pulmonary vascular tension through Ca^{2+}-activated or voltage-sensitive K^+ channels, at least in isolated rabbit lungs.[128] Halothane- and enflurane-induced constriction of pulmonary vessels was potentiated by voltage-gated potassium (Kv) channel inhibition in this isolated rabbit lung preparation. In contrast, isoflurane did not affect pulmonary vessels when Kv channels were inhibited. Further, sevoflurane dilated pulmonary vessels and this dilation was unaffected by K^+ channel subtype inhibitors (Fig. 21.10).[128]

Smooth muscle TASK-1 channels also appear to contribute to volatile anesthetic–induced PA dilation.[129] Rather than causing immediate vasodilation, volatile anesthetics produce a paradoxical initial dose-dependent increase in force in isolated PA strips as a result of Ca^{2+} release from intracellular stores (Fig. 21.11).[122,130,131] Subsequently, a decrease in force, associated with a Ca^{2+}/calmodulin–dependent protein kinase II activation, occurs.[130,131] Extrapolation of these results to humans must be approached with caution, but these studies suggest that vasodilatory responses of volatile anesthetics may be more profound in patients with reduced SR Ca^{2+} stores (e.g., neonates) or those with depressed protein kinase activity (e.g., primary pulmonary hypertension).

In general, all volatile anesthetics attenuate HPV in isolated perfused lungs or in an in situ preparation with constant perfusion (Fig. 21.12),[121,132] whereas most intravenous anesthetics do not have such an effect.[118] The combined administration of a Ca^{2+}-channel blocker and a volatile anesthetic further reduces HPV by up to 40%, compared with either drug alone, suggesting that these drugs inhibit HPV through differing mechanisms. The mechanisms of HPV inhibition by volatile anesthetics are unclear but may be related to arachidonic acid metabolites[133]

or endothelial-derived vasodilating factors.[134] However, other evidence suggests that anesthetic-induced inhibition of HPV may occur independent of pulmonary vascular endothelium, NO, or guanylate cyclase.[135,136] Volatile anesthetics also disrupt Ca^{2+} homeostasis in vascular smooth muscle and thereby interfere with pulmonary vasoconstriction. Halothane and isoflurane attenuated endothelium-dependent vasodilation by inhibiting cGMP accumulation[137] and a K_{ATP} channel-mediated interaction between NO and prostacyclin in isolated canine PA rings.[138] In contrast, isoflurane modulated the HPV response, at least in part, through Ca^{2+}-activated and voltage-sensitive K^+ channels. Attenuation of HPV by sevoflurane occurred independent of K^+-channel function.[139]

Fig. 21.11 (A) Proposed signaling pathways underlying volatile anesthetic-induced contraction and relaxation in pulmonary artery smooth muscle. Intracellular calcium *(ICa^{2+})* may be increased by release from the sarcoplasmic reticulum *(SR)*, by the inhibition of voltage-sensitive potassium *(K_v)* or calcium-activated potassium *(K_{ca})* channels, or by receptor-operated Ca^{2+} channels *(ROCC)*. Increased ICa^{2+} results in an initial dose-dependent increase in force (associated with activation of protein kinase C *[PKC]* and increased mitogen-activated protein kinase *[MAPK]*). Volatile anesthetics also decrease ICa^{2+} by activating adenosine triphosphate–regulated potassium *(K_{ATP})* channels, thereby inhibiting Ca^{2+} influx via voltage-operated Ca^{2+} channels *(VOCC)*, decreasing SR-induced release of Ca^{2+}, inhibiting the phosphatidylinositol *(Pi)* cascade, and enhancing SR-mediated reuptake of Ca^{2+}. The resultant decrease in force is associated with activation of Ca^{2+}-calmodulin-dependent protein kinase II *(CaMKII)*. It is important to note that there are many agent-specific effects of volatile anesthetics on each component of these pathways. *pERK,* Phosphorylated extracellular signal-regulated kinase. Desflurane inhibits hypoxic pulmonary vasoconstriction in isolated rabbit lungs. *Anesthesiology*. 1995;83:552. Used with permission.)

The relative efficacy of volatile anesthetics on HPV in vivo is difficult to assess because several other factors impair HPV, including temperature, pH, CO_2 tension, degree of hypoxia, size of the hypoxic area, surgical trauma, and medications. During OLV, the direct inhibitory effects of volatile anesthetics on HPV may increase perfusion in the nonventilated lung and worsen hypoxemia. However, volatile anesthetics may also affect HPV, lung perfusion, and oxygenation by indirect actions on cardiac output and mixed venous O_2 saturation.[140] Baseline PA blood flow and pressure also modulate the effects of HPV. Elevated PA pressures may cause passive distension of constricted vascular beds and thereby reverse HPV. Alternatively, reflex pulmonary and systemic vasoconstriction in response to hypotension may increase PVR in healthy lung segments, leading to a shift of pulmonary blood flow to hypoxic areas of lung.[121]

Early studies suggested that nitrous oxide attenuates HPV in animal models in vivo. As opposed to the findings with isoflurane,[133] sevoflurane or desflurane did not inhibit HPV in chronically instrumented dogs subjected to gradual occlusion of the right main PA (Fig. 21.13).[141] Nitrous oxide,[142] desflurane, and isoflurane,[143] but not xenon,[142] reduced the mixed venous O_2 saturation, cardiac output, and arterial oxygenation during OLV in pigs. However, nitrous oxide,[142] xenon,[142] desflurane,[143,144] and isoflurane[143,145] did not alter perfusion of the nonventilated lung or reduce the shunt fraction during OLV. In animals with a preexisting impairment of gas exchange attributable to a pneumoperitoneum, sevoflurane, but not isoflurane, caused more profound abnormalities in gas exchange than did propofol.[146] Thus although reductions in HPV by volatile anesthetics have been relatively small in vivo, preexisting pulmonary disease may worsen anesthetic-induced gas exchange abnormalities.

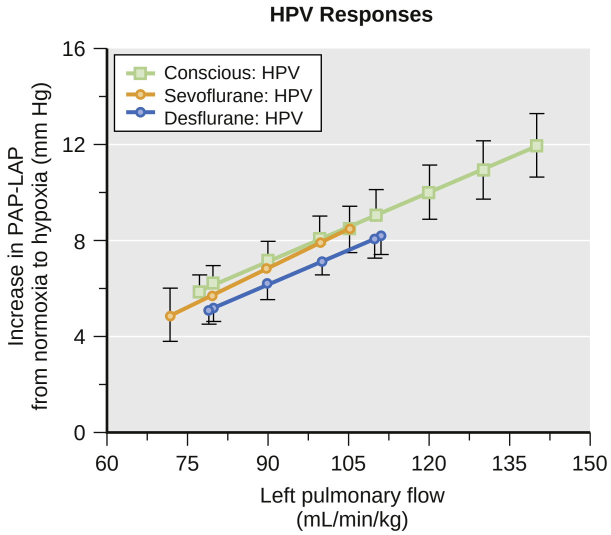

Fig. 21.13 Composite hypoxic pulmonary vasoconstriction *(HPV)* responses (increase in pulmonary artery pressure *[PAP]* minus left atrial pressure *[LAP]* as a function of left pulmonary flow in the same seven chronically instrumented dogs in the conscious state and during sevoflurane and desflurane anesthesia. Neither anesthetic affected the magnitude of HPV when compared with the response in the conscious state. (From Lesitsky MA, Davis S, Murray PA. Preservation of hypoxic pulmonary vasoconstriction during sevoflurane and desflurane anesthesia compared to the conscious state in chronically instrumented dogs. *Anesthesiology*. 1998;89:1501. Used with permission.)

EFFECTS OF VOLATILE ANESTHETICS ON PULMONARY VASCULATURE IN HUMANS

General anesthesia often impairs pulmonary gas exchange. In addition to specific effects of volatile anesthetics, many other factors including gravity, posture, atelectasis, differences in vessel conductance between lung regions, intrathoracic pressure, and HPV may all affect the distribution of pulmonary blood flow and ventilation during the administration of volatile anesthetics. Alterations in regional ventilation are related to variations in alveolar compliance, inspiratory rate, flow rate, pleural pressures, and ventilatory modes.[147] In spontaneously breathing healthy volunteers, sevoflurane (1 MAC for 20 minutes) administered via a facemask did not alter the relative distribution of either ventilation or perfusion in a ventral to dorsal direction measured by single photon–emission CT.[147] Similarly, no change in the distribution of ventilation, as measured by using electrical impedance tomography, occurred in spontaneously breathing adults receiving 0.7 MAC of sevoflurane via a laryngeal mask airway (LMA).[145] Interestingly, sevoflurane reduced regional heterogeneity of the perfusion distribution and increased regional heterogeneity of the ventilation/perfusion ($\dot{V}/\dot{Q}$) ratio with a tendency toward lower ratios in spontaneously breathing volunteers.[147] This alteration may contribute to less effective pulmonary gas exchange, but these effects were relatively small compared with alterations in $\dot{V}/\dot{Q}$ distribution that occur during mechanical ventilation.[148,149] Either pressure-controlled or pressure-supported ventilation with sevoflurane caused similar ventral redistributions of ventilation.[148]

Isoflurane produces no clinically significant effects on pulmonary shunt in healthy patients even at concentrations that cause systemic hypotension.[150] Thoracic surgeries are usually performed in the lateral position with an open chest and dramatically affect the relative distribution of ventilation and perfusion. Under these conditions, a diseased, nondependent lung may affect the pulmonary vascular response to hypoxia, as may surgical manipulation of the lung itself. Most studies in animal models or patients undergoing OLV did not demonstrate clinically significant attenuation of HPV by volatile anesthetics. Differences in shunt fraction, PVR, or oxygenation between isoflurane and sevoflurane anesthesia in patients undergoing OLV for lobectomy for lung cancer do not appear to be significant.[151] Some studies also demonstrated that shunt fraction is similar in patients receiving propofol or either isoflurane[152] or sevoflurane[153,154] during OLV. No significant differences in shunt fraction or arterial O_2 tension were observed during intravenous infusions of ketamine, which does not inhibit HPV, and inhalation of enflurane. In contrast, isoflurane[155,156] and sevoflurane[156] impaired oxygenation and increased shunt fraction more than an intravenous infusion of propofol during OLV. However, the differences in oxygenation observed in these studies were small and clinically insignificant. The relative depth of anesthesia may affect interpretation of the differences in oxygenation between intravenous and volatile anesthetics in these studies. When doses of propofol and sevoflurane were chosen based on a similar depth of anesthesia, assessed by a bispectral index monitor, similar reductions in arterial oxygenation were observed in patients undergoing OLV.[154] Similar changes in shunt fraction and oxygenation were shown to occur with halothane,[157] isoflurane,[151,157,158] desflurane,[158] and sevoflurane in patients undergoing thoracotomy and OLV (Fig. 21.14).[151,156-158]

Convincing evidence suggests that all volatile anesthetics may be safely used in patients undergoing thoracotomy and OLV. The increase in shunt and the decrease in oxygenation caused by halothane or isoflurane[157] were consistent with an approximately 20% inhibition of HPV at 1 MAC. Instead of the expected 50% reduction in pulmonary blood flow in a hypoxic lung in the absence of a volatile anesthetic, blood flow decreases by 40% during hypoxia in the presence of 1 MAC isoflurane. This change in flow corresponds to an increase in pulmonary shunt by approximately 4% of the cardiac output. Carlsson and colleagues[159] applied multiple inert gas elimination techniques to measure the true shunt fraction in humans anesthetized with volatile anesthetics and demonstrated a 2% to 3% increase in shunt fraction corresponding to approximately 20% HPV inhibition at 1.5% isoflurane. In addition, no significant effects on arterial oxygenation occurred with clinically relevant concentrations of isoflurane or enflurane. Indeed, the use of total intravenous anesthesia with propofol and alfentanil did not reduce the occurrence of hypoxemia during OLV, compared with a volatile anesthetic.[152]

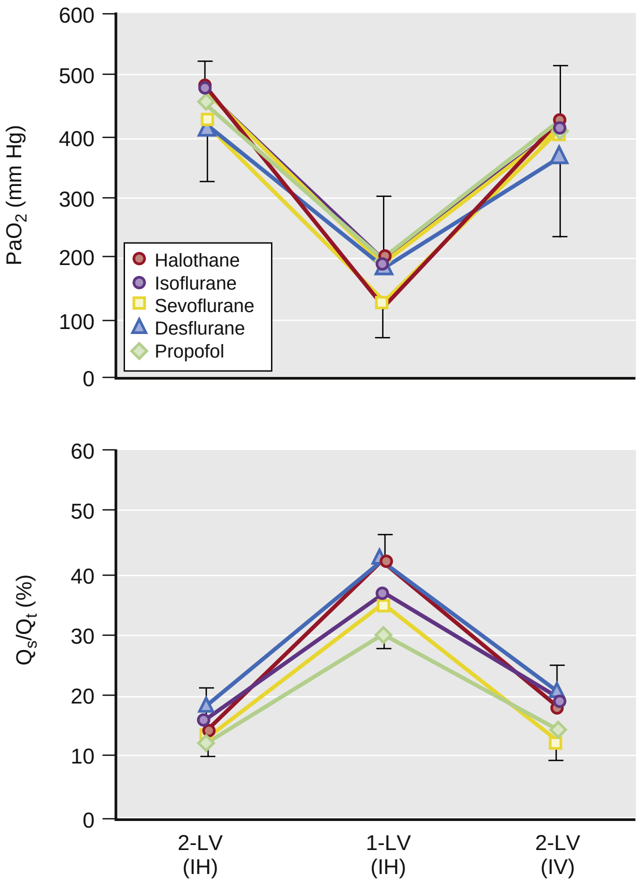

Fig. 21.14 Partial arterial pressure of oxygen *(PaO_2)* and intrapulmonary shunt fraction *(Q_s/Q_t)* in patients with both lungs ventilated *(2-LV)* or with one lung ventilated *(1-LV)*. Patients received an inhaled agent *(IH)* halothane, isoflurane, sevoflurane, or desflurane or the intravenous *(IV)* anesthetic propofol. Note the minimal effect on PaO_2 and shunt fraction that occurs in changing from a volatile anesthetic to an IV agent. (Data modified from Abe and colleagues,[148,153] Benumof and colleagues,[154] and Pagel and colleagues.[155])

Functionally, volatile anesthetics exert only mild, if any, inhibitory effects on HPV and oxygenation.[160,161] The relatively small inhibition of HPV should not significantly influence clinical decision making, especially considering the efficacy of drugs such as the peripheral chemoreceptor agonist, almitrine[162] (which enhances HPV), or inhaled NO (which selectively increases perfusion to adequately ventilated pulmonary regions). In addition, ventilatory strategies (e.g., nondependent lung continuous positive airway pressure, permissive hypercapnia) and fiberoptic bronchoscopy to ensure proper positioning of a double-lumen endotracheal tube help alleviate hypoxemia. The net effect of volatile anesthetics on HPV is multifactorial and depends on the direct effects of these agents not only on pulmonary vasomotor tone, but also by indirect actions that occur during anesthesia and surgery.

Fig. 21.15 Anatomic components of the respiratory system and the main nuclei involved in the generation of respiration from chemoreception to motoneuron activation (see text for details). Wakefulness drive is derived from the lateral hypothalamus. The *central pattern generator*, where respiratory drive is converted into a respiratory pattern, is thought to consist of several nuclei in the medulla and pons. Potential sites of central chemoreception are the locus coeruleus, areas A5 and A7, in the pons, and the medullary raphé and retrotrapezoid nucleus in the medulla. Expiratory and inspiratory excitatory drive is relayed to premotor neurons (ventral respiratory group), which project to expiratory motoneurons and inspiratory motoneurons (e.g., phrenic nerve) in the spinal cord. These motor nerves innervate abdominal muscles (expiratory) and diaphragm (inspiratory). Respiratory pattern and chemoreception are influenced by afferents from the lungs and carotid bodies. Excitatory inputs *(red arrows)*; inhibitory inputs *(blue buttons)*.

CONTROL OF RESPIRATION

Components of the Respiratory Regulatory System

The regulation of respiratory function is very complex, occurs both on unconscious and conscious levels, and is precisely controlled by neuronal circuits, which are mainly located in the brainstem and include the medulla oblongata, pons, and midbrain (Fig. 21.15).

The neuronal networks in these areas are sufficient to generate involuntary, automatic breathing, which may be superseded by cortical centers for voluntary efforts such as speech, swallowing, laughing, sneezing, and coughing. Respiration per se is to ensure adequate gas exchange in order to meet metabolic demand during various levels of activity. Reflex inputs from the upper airways, lungs, and carotid bodies modulate respiration when inadequacy of gas exchange is sensed. Connections to the lateral hypothalamus also convey wakefulness drive to the respiratory center. Physiological status like sleep and pregnancy alter the respiratory function; so does nonphysiological status such as sedation. This chapter is not intended to discuss respiratory physiology in detail. Rather, its focus is on the major regulatory components of the respiratory system and how they are affected by inhalational anesthetics (Fig. 21.16).

Readers are referred to Chapters 13 and 41 for a detailed discussion of respiratory physiology and monitoring.

In general, respiratory drive is suppressed by all inhalational anesthetics except nitrous oxide.[163,164] Volatile anesthetics decrease glutamatergic excitatory drive to bulbospinal respiratory neurons and increase $GABA_A$ergic inhibitory mechanisms at the postsynaptic neuronal membrane.[165] In hypoglossal upper airway motor neurons, volatile anesthetics hyperpolarize neuronal membrane resting potential by activating K^+ channels that are linked to serotonin or norepinephrine receptors.[166,167] The magnitude of respiratory depression by volatile anesthetics may also depend on the position of the neuron in the neuronal hierarchy, which extends from the neurons generating excitatory respiratory drive to the respiratory pattern generator

Fig. 21.16 (A) Ligand-gated receptors and ion channels on respiratory-related neurons. Excitatory receptors and channels are marked in *yellow*, inhibitory in *blue*. Opening of pH sensitive channels excites the neuron, whereas the opening of two-pore domain, acid-sensitive potassium (K^+) *(TASK)* channels causes membrane hyperpolarization and inhibition of neuronal discharge. (B) Effects of volatile anesthetics on respiratory-related neurons. Volatile anesthetics eliminate wakefulness drive to the respiratory system *(red cross out)*. *Black arrows* indicate changes in receptor function (*up*, increase; *down*, decrease) that have been published in the literature. Volatile anesthetics reduce the presynaptic release of glutamate and γ-aminobutyric acid A *($GABA_A$)* in respiratory premotor neurons. The cumulative anesthetic effects on the respective neuron groups are depicted *(red arrows)*. The relative magnitude of the depressant effect is visualized *(number of arrows)*. In humans, peripheral chemodrive is significantly more depressed than central chemodrive. Upper airway motoneurons are significantly more depressed than inspiratory motoneurons. *$5\text{-}HT_2$*, 5-Hydroxytryptamine; *AMPA*, alpha-amino-3-hydroxy-5-methyl-4-isoxazolepropionate acid; *NMDA*, *N*-methyl-D-aspartate; *NTS*, nucleus of the solitary tract.

and down to the phrenic and hypoglossal respiratory output motor neurons (see Fig. 21.16). Consequently, volatile anesthetics, which strongly affect synaptic neurotransmission, have a greater depressant effect on polysynaptic neuronal circuits that include many synapses, compared with those comprised of only few neurons (paucisynaptic). Fortunately, most connections between the single components of the respiratory system seem to be paucisynaptic, which may explain a relative resistance of automatic breathing to the depressant effects of volatile anesthetics.

The depressant effect of inhalational anesthetics on respiratory system may be further demonstrated at the molecular and genetic levels. Heterozygous paired-like homeobox 2b (PHOX2B) gene mutations have been found in the majority of patients diagnosed with late-onset central hypoventilation syndrome and may increase sensitivity of those patients to anesthetic-induced depression of breathing.[168] A recent study demonstrated that isoflurane can potentiate aggregation and mislocalization of PHOX2B variants, alter protein folding, and induce endoplasmic reticulum stress, indicating a mechanism by which these agents may affect respiratory neuronal function after surgery and promote the onset of the neurologic respiratory disease.[169]

Importantly, most data on respiratory regulatory systems are derived from animal models and may not directly translate to humans, as summarized in a review by Forster and Smith.[170] This section will therefore cover important animal study results to help understand the basic respiratory structure and function, as well as present recent clinical studies demonstrating the correlation of those findings to clinical practice.

CENTRAL CHEMORECEPTION

For many years, the prevailing view was that CO_2/H^+ sensitivity was due exclusively to the central chemoreceptors. Recent studies showed that central chemoreceptors contribute about two thirds of the ventilatory response to CO_2/H^+, while peripheral chemoreceptors contribute about one third.[170] These excitatory chemodrive mechanisms ensure automatic breathing under normoxic, normocapnic conditions in healthy individuals.[170] Central chemoreceptors discharge in response to the decrease in extracellular pH or an increase in [H$^+$]. In addition, they project to other areas of the respiratory system where they form excitatory synapses. This pathway is well recognized, but its exact location remains to be defined. Animal studies have pointed to multiple chemosensitive sites in the brainstem[171] including the retrotrapezoid nucleus (RTN), medullary raphé, locus coeruleus, nucleus tractus solitarius (NTS), lateral hypothalamus, and caudal ventrolateral medulla. The RTN is a particularly strong candidate as the absence of RTN likely causes severe central apneas in congenital central hypoventilation syndrome. Glial cells in these areas may also theoretically contribute to chemoreception through their effect on extracellular pH or by hypoxia- or CO_2-induced ATP release potentially altering the function of chemosensitive neurons.[172]

Central chemoreceptors also promote excitatory drive to neurons regulating upper airway patency and arousal from sleep.[171] The genioglossus muscle, considered a typical representative for the muscles maintaining upper airway patency, receives significant tonic and phasic excitatory drive in the conscious state. Genioglossal muscle activity is reduced during sleep, but high levels of inspiratory CO_2 (>5%) are capable of recruiting near-normal levels of phasic activity. This phenomenon does not occur during rapid eye movement (REM) sleep because genioglossal muscle activity is absent, and therefore the upper airway collapses and hypoventilation follows.

Hypercapnia secondary to upper airway obstruction and hypoventilation may recruit the normal phasic activity of genioglossal muscle through central chemoreceptors and function as another mechanism (aside from hypoxia) by which patients with obstructive sleep apnea (OSA) arouse from sleep and reestablish airway patency. Residual subanesthetic concentrations of volatile anesthetics, which may be present for hours in postoperative patients, inhibit both peripheral hypoxic[173] and CO_2 chemosensitivity[174] and may also substantially impair the spontaneous arousal and resolution of upper airway obstruction that would otherwise occur with severe hypoxia or hypercarbia. This is a particularly important issue to recognize for same-day surgery patients, especially with a history of OSA.[175]

CENTRAL PATTERN GENERATOR

The cyclic breathing pattern is controlled by the central pattern generator (CPG). A recent review by Abdala and colleagues nicely summarizes the progress in the field.[176] Even though several models of the CPG network have been proposed, many of the circuit interactions and their functionalities remain unknown. CPG is believed to be located in nuclei of the pontomedullary network (see Fig. 21.15).[177] In the related nuclei, the network consists of excitatory and inhibitory neurons that control the inspiratory and expiratory phase of breathing. The breathing cycle is complexly regulated, and the type of neurons and the related neurotransmitters have been well illustrated (Fig. 21.17). This neuronal circuit can be pharmacologically modulated by inhaled anesthetics, affecting respiratory rate, upper airway patency, and relative contributions of the chest wall versus the diaphragm to tidal volume and minute alveolar ventilation.

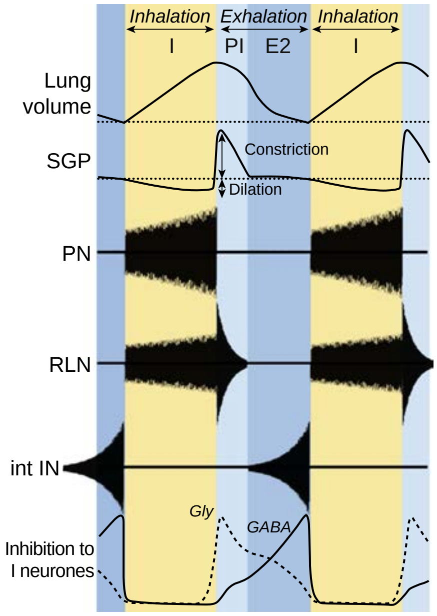

Fig. 21.17 Schematic diagram of a three–phase respiratory cycle and its neuro–mechanical components. Top schematic plots and neurograms represent lung volume, subglottal pressure *(SGP)*, phrenic *(PN)*, recurrent laryngeal *(RLN)*, and internal intercostal *(int IN)* nerve activities during the three phases of a respiratory cycle, i.e., inspiration *(I)*, postinspiration *(PI)*, and late expiration *(E2)*. Note that RLN conveys outputs from both abductor and adductor motoneurones, which fire respectively during inspiration (to dilate the glottis during inhalation) and postinspiration (to narrow the glottis during exhalation). Bottom overlay plots represent hypothetical time courses of glycine– *(Gly, dotted line)* and GABA–mediated *(continuous line)* inhibition to inspiratory (I) neurones during the respiratory cycle. These time courses reflect the activity of medullary postinspiratory (PI) inhibitory neurones, thought to be predominantly glycinergic, and GABAergic augmenting expiratory (E–AUG) inhibitory neurones active during E2 phase, both of which inhibit inspiratory neurones during expiration. Phasic inhibition of inspiratory neurones is minimal during inspiration, when active inspiratory neurones inhibit expiratory neurones, but rises abruptly during PI to orchestrate the inspiratory–expiratory phase transition and initiate exhalation. (Redrawn from Abdala AP, Paton JF, Smith JC. Defining inhibitory neurone function in respiratory circuits: opportunities with optogenetics? *J Physiol.* 2015;593[14]:3033–3046. INTEGRATION OF PERIPHERAL INPUTS

Afferent inputs from the periphery reach the brainstem respiratory center and influence respiratory drive. These inputs include the carotid body chemoreceptors, vagal inputs from the lungs and airways, and pulmonary baroreceptor inputs. The carotid body is the major peripheral chemoreceptor. It senses hypoxia or hypercapnia, which in turn increases carotid sinus nerve discharge. This information then reaches the RPG via NTS glutamatergic neurons, which also targets rostral ventrolateral medulla presympathetic neurons thereby raising sympathetic nerve activity (SNA). Chemoreceptors also regulate presympathetic neurons and cardio VPN indirectly via inputs from the RPG.[178] In essential hypertension, OSA, and congestive heart failure, chronically elevated carotid body afferent activity contributes to increasing SNA but breathing remains unchanged or becomes periodic.

The function of the carotid body was discovered nearly 80 years ago, and for a long time it was thought that the carotid body chemoreceptors function independently from central chemoreceptors.[179] However, more recent studies suggested that the peripheral and central chemoreceptors are not functionally separate but are interdependent. The sensitivity of the medullary chemoreceptors is critically determined by input from the peripheral chemoreceptors and possibly other breathing-related reflex afferents as well.[170] This effect might be mediated through interactions within the NTS and/or through NTS projections to parafacial respiratory group/RTN integrating neurons and/or through projections to neurons of a raphe-pontomedullary respiratory network.

Afferent vagal inputs from the lungs and airways are also relayed through the NTS. Pulmonary baroreceptor inputs project to second-order pump neurons in the NTS, which can provide both excitatory and inhibitory inputs to various parts of the medullary respiratory column. In general, pulmonary baroreceptor inputs promote the phase switch from inspiration to expiration. This vagal expiratory-facilitating reflex (Hering-Breuer reflex) is most prominent in immature mammals but also modulates respiratory phase-timing during resting ventilation in adult humans.[180] Although some of these inputs directly influence the CPG, others are integrated at the level of the bulbospinal or premotor neurons, which project to the motor neurons in the spinal cord.

RESPIRATORY MOTOR OUTPUT AND UPPER AIRWAY PATENCY

The pontomedullary respiratory network generates the respiratory pattern and then projects to and controls respiratory motor outputs in the brainstem and spinal cord. The phrenic motor neurons are the main inspiratory neurons in the spinal cord. They are located at the levels C_3 to C_5 of the spinal cord and innervate the diaphragm.[177] Phrenic motor neurons are also directly depressed by volatile anesthetics.[181] Expiratory motor neurons are located at approximately T_7-T_{12} of the spinal cord and innervate truncal abdominal muscles that aid with forceful expiration and with expiratory expulsive efforts such as coughing. Expiratory motor neurons receive inputs from expiratory bulbospinal neurons and the pons.[177] The spinal motor neurons are the final neurons in the respiratory neuronal hierarchy. Their activity tends to be reduced by the cumulative effect of anesthetics on all previous steps of chemoreception and neurotransmission.

To ensure effective ventilation, inspiratory muscle activity needs to be closely coordinated with upper airway muscles that maintain airway patency. Central respiratory motor output almost simultaneously engages both the phrenic motor neurons (serving chest wall pump muscles) and hypoglossal motor neurons (serving pharyngeal muscle dilators).[182,183] The hypoglossal motor nerve innervates upper airway muscles, particularly the genioglossal muscle. The strength of excitatory and inhibitory drive to hypoglossal motor neurons strongly depends on the level of consciousness and differs between the REM and non-REM sleep phases.

The onset of the sleeping state results in a reduced tonic activation of upper airway dilator musculature and enhances collapsibility. This effect is especially problematic for patients with OSA whose airway is narrower, longer, and more collapsible than that of those without OSA. Patients with OSA critically rely on compensatory activation of airway dilator muscles to maintain patency during wakefulness. The reduced lung volumes in obese recumbent patients during sleep also decrease caudal traction on the trachea, promoting pharyngeal collapse.[184,185] In addition, the loss of wakefulness removes an important vigilance component in the ventilatory control system, leaving the regulation of central respiratory motor output largely under chemoreceptor and mechanoreceptor feedback control.

The mechanisms of airway collapse during sleep and anesthesia are closely related. Hypoventilation and/or hypoxia secondary to upper airway collapse during anesthesia/sedation represent a significant challenge for anesthesia care providers, particularly in ambulatory surgery patients. The effect of inhalational anesthetics on pharyngeal airway collapsibility can best be illustrated by visualizing the changes as the depth of sedation increases.

EFFECTS OF INHALED ANESTHETICS ON RESTING VENTILATION

Volatile anesthetics suppress conscious control of breathing at concentrations of less than 1 MAC and completely abolish conscious breathing drive at higher concentrations. Breathing is then largely controlled by automatic brainstem mechanisms and chemoreflex inputs. All volatile anesthetics also cause a dose-dependent decrease in minute ventilation at concentrations greater than 1 MAC because of a decrease in tidal volume. However, in a pressure chamber, Hornbein and colleagues demonstrated that nitrous oxide does not significantly reduce minute ventilation within 1.5 MAC (well beyond an atmosphere).[186] The respiratory rate typically increases for all inhalational agents tested, except for xenon, which causes a significant reduction in respiratory rate (Fig. 21.18). Indeed, there are several reports indicating that xenon can cause hypopnea or apnea.[187,188]

Most volatile anesthetics cause an increase in respiratory rate by producing a decrease in both inspiratory and expiratory duration, whereas opioids cause a very prominent decrease in respiratory rate that primarily results from a large increase in expiratory duration. However, the observed modest decrease in minute ventilation with volatile anesthetics could underestimate the magnitude of the respiratory depressant effects of these agents. This is due to volatile anesthetic–induced hypoventilation increasing $PaCO_2$ in a closed central chemoreflex feedback loop. In turn, central chemoreceptors are stimulated, thereby increasing central chemodrive to the respiratory center and increasing minute ventilation.[199-202]

EFFECTS OF INHALED ANESTHETICS ON CHEMOREFLEXES

Volatile anesthetics impair peripheral chemoreceptor responses to hypoxia and hypercarbia in a dose dependent manner. In the presence of volatile anesthetic concentrations of 1 MAC or higher, breathing in humans is entirely dependent on the automatic control from the pontomedullary respiratory center and afferent excitatory inputs from the central chemoreceptors. These anesthetic concentrations lead to a complete depression of the peripheral chemoreflex loop with further respiratory depression rather than

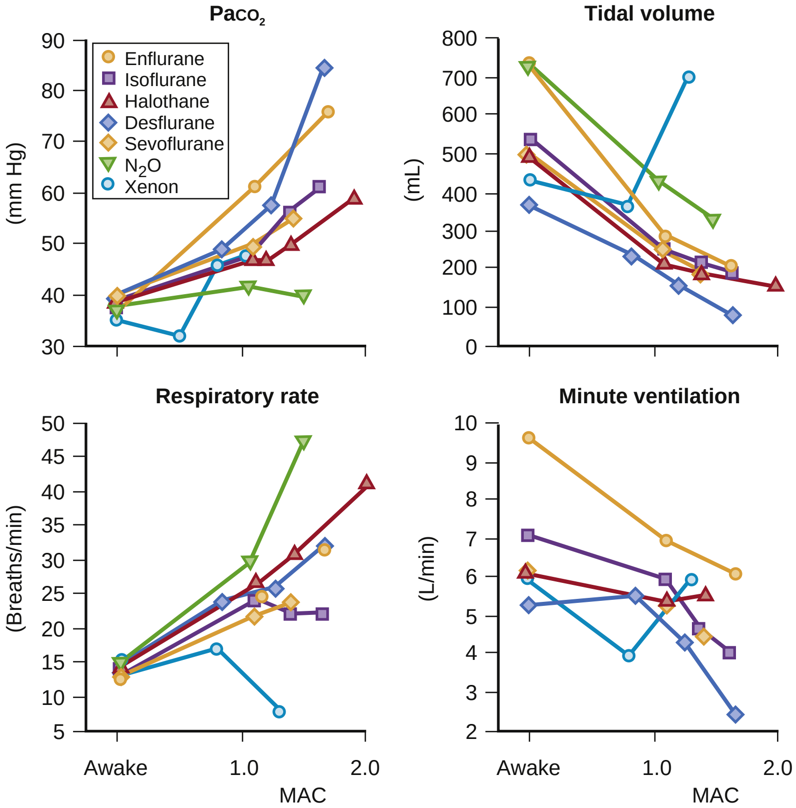

Fig. 21.18 Comparison of mean changes in resting partial arterial pressure of carbon dioxide ($PaCO_2$), tidal volume, respiratory rate, and minute ventilation in patients anesthetized with various inhaled agents. Most agents cause dose-dependent tachypnea, decreases in minute ventilation and tidal volume, and an increase in $Paco_2$. *MAC,* Minimum alveolar concentration, *N_2O,* nitrous oxide.[189-194] *Note: data for xenon has been extrapolated from references.*[195-198]

stimulation in response to hypoxia.[203] Even very low concentrations of the agent (0.1 MAC of isoflurane and sevoflurane) depress the peripheral chemoreflex loop, without affecting the central chemoreflex loop. Desflurane at the same MAC showed no effect on peripheral and central CO_2 sensitivity.[204] A loss of upper airway muscle tone and function accompanies this process, as does differential depression of neurotransmission at the level of the spinal cord.[205]

The effect of inhaled anesthetics on respiratory drive may not be clinically relevant in the patient undergoing controlled ventilation. However, it does matter in spontaneously breathing patients. Because the suppressive effect of inhaled anesthetics on respiratory drive is synergetic with narcotics and frequently these two drug classes are administered concurrently, the suppression on the hypoxic and hypercarbic drive can increase the risk of postoperative respiratory complications.

EFFECTS OF INHALED ANESTHETICS ON THE HYPERCAPNIC VENTILATORY RESPONSE

In awake humans, about one third of the CO_2-mediated respiratory drive is through peripheral chemoreceptors and other two thirds through the central chemoreceptors. The respiratory drive mediated by the peripheral chemoreceptors is augmented by hypoxia.[206] However, the hypoxia-mediated component is abolished by the majority of volatile anesthetics at concentration even under 1 MAC. When the anesthetic concentration increases above 1 MAC, the peripheral chemoreceptor-mediated portion of the CO_2 responsive respiratory drive are abolished, and only the central chemoreceptor loop remains functional.[173,207-209] Depression of the respiratory drive is often described in a quantitative manner by plotting the CO_2 response curve (an increase in $PaCO_2$ vs. an increase in minute alveolar ventilation). Volatile anesthetics also cause a rightward shift of the apneic threshold,[210] that is the minimum $PaCO_2$ required to initiate spontaneous respiration. Thus spontaneous breathing efforts do not occur if mechanical or assisted ventilation efforts drive the $PaCO_2$ levels below the CO_2 threshold during anesthesia.[211]

Patients under general anesthesia with volatile anesthetics become hypercarbic if they are spontaneously breathing without any ventilatory support. Pressure support ventilation is often used to counteract the suppression of the respiratory drive by the volatile anesthetics. However, it remains to be determined if an increase in pressure support would lead to a proportional increase in minute alveolar ventilation as the intrinsic CO_2 response curve at a given level of sedation is not altered. An increase in minute alveolar ventilation secondary to increased tidal volumes from pressure support may result in a decreased respiratory rate and therefore minute alveolar ventilation may not be increased as much as expected.

EFFECTS OF VOLATILE ANESTHETIC ON THE HYPOXIC VENTILATORY RESPONSE IN HUMANS

Hypoxic ventilatory response (HVR) is rarely encountered in conscious healthy humans at sea level. However, for

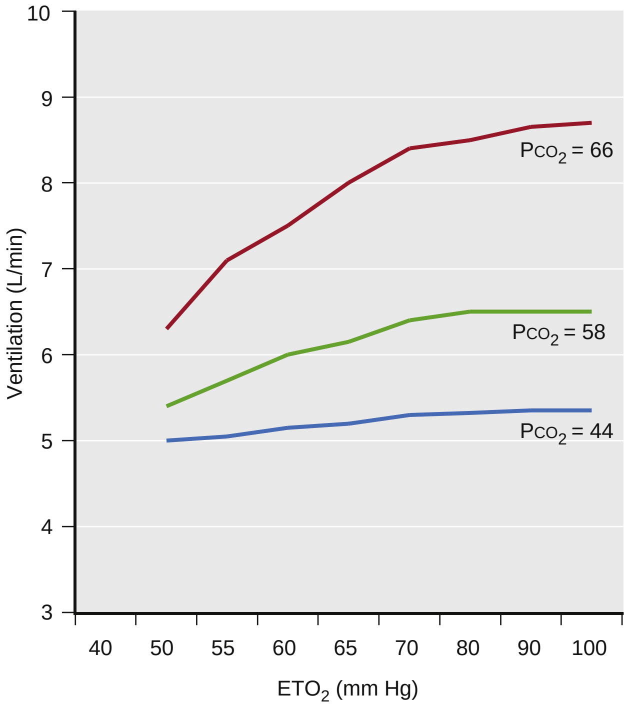

Fig. 21.19 Effects of halothane anesthesia on the hypoxic ventilatory response in humans at three steady-state levels of partial pressure of carbon dioxide (PCO_2). Halothane anesthesia (1.1 minimum alveolar concentration) completely eliminates the hypoxic ventilatory response and the hypoxic hypercapnic interaction at the peripheral chemoreceptors. *ETO_2*, End-tidal oxygen. (Modified from Knill RL, Gelb AW. Ventilatory responses to hypoxia and hypercapnia during halothane sedation and anesthesia in man. *Anesthesiology*. 1978;49:244. Used with permission.)

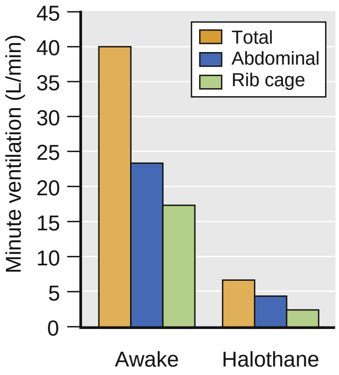

Fig. 21.20 Effects of halothane anesthesia on rib cage and abdominal ventilation during hypercapnia (calculated ventilation at partial arterial pressure of carbon dioxide [$PaCO_2$] of 55 mm Hg). Compared with being awake, halothane anesthesia strongly depresses minute ventilation. Halothane depresses the rib cage component to ventilation more than the abdominal component (diaphragmatic). Data are means. (Graph is based on data from Warner DO, Warner MA, Ritman EL. Mechanical significance of respiratory muscle activity in humans during halothane anesthesia. *Anesthesiology*. 1996;84:309.)

special occupations, such as tunnel workers at sea level, or mountain climbers staying at high attitude, hypoxia does occur and therefore the HVR becomes an important mechanism to compensate for low inspired O_2 concentrations. One example is humans living at high altitude. At the top of Mt. Everest (8848 m), the partial pressure of O_2 of ambient air is only about 50 mm Hg compared with 159.6 mm Hg at sea level. The corresponding arterial blood PaO_2 is only 37.6 mm Hg, which is lower than the partial pressure of O_2 in the mixed venous blood in healthy resting adults living at sea level. The estimated minute ventilation is approximately 166 L/min as a result of severe hypoxic hyperventilation.[212] However, this powerful compensation mechanism is significantly comprised under anesthesia with volatile anesthetics under 1 MAC and completely abolished at 1.1 MAC of halothane (Fig. 21.19). It is important to realize that even a subanesthetic concentration (0.1 MAC) of inhalational anesthetics profoundly diminishes hypoxic respiratory drive without concurrent use of narcotics.[213] The potency of the suppression of HVR has been proposed as the following order: halothane > enflurane > sevoflurane > isoflurane > desflurane.[173]

Certain patient populations are particularly vulnerable to the inhibition of hypoxic respiratory drive at subanesthetic concentrations, including premature infants and patients with OSA.[214,215] The depressant effect on the HVR is due to selective inhibition of the peripheral chemoreflex loop. The carotid body appears to be the most likely target. However, the mechanisms by which subanesthetic concentrations of volatile anesthetics attenuate hypoxic ventilatory drive are not completely understood. Interestingly, acute pain and central nervous system arousal do not restore impaired HVR during sevoflurane sedation. Thus compromise of the central nervous system arousal state per se does not contribute to the impairment of the acute HVR by sevoflurane.[216] Additionally, audiovisual stimulation does not prevent the blunting of acute HVR by low-dose halothane, but by isoflurane. This finding raises the possibility that volatile anesthetics might differently affect the hypoxic chemoreflex loop.[217]

EFFECTS OF INHALED ANESTHETICS ON RESPIRATORY MUSCLE ACTIVITY

Humans are bipeds and very different from the quadruped mammals in terms of contribution of various muscle groups, particularly the truncal muscles, to the normal respiratory effort, probably due to differences in posture. Thus the results of respiratory control studies in animals could not be directly extrapolated to humans, whether under normal resting conditions or under anesthesia. At quiet breathing in supine and conscious nonpregnant adult humans, scalene and parasternal inspiratory activity is universally present, but abdominal expiratory activity is absent.[218,219] This means that at quiet breathing, expiration is mostly passive and likely occurs via recoiling of chest wall and lungs. When breathing is stimulated by inhaling CO_2, the inspiratory activity is enhanced and expiratory muscles are recruited.

Volatile anesthetics, such as halothane, depress various respiratory muscles differently (Fig. 21.20). The diaphragm, as the main inspiratory muscle, is unique in that regard because it is relatively spared from the respiratory depression by volatile anesthetics, probably because of its low position in the hierarchy of the neurotransmission system. At 1 MAC of halothane, the tidal volume was reduced by 59%, respiratory rate was increased by 146%, and FRC was decreased by 335 ± 75 mL. The decrease in minute ventilation could be because of rib cage/chest wall activity but is not because of a reduction in abdominal breathing, and the contribution of the diaphragm is also substantially less affected.[220] Abdominal expiratory activity is routinely recruited during halothane anesthesia in male subjects.

The depressive effect of halothane on respiratory muscle is also gender dependent. Of note, pregnancy significantly alters the physiology and contribution of each respiratory muscle groups. The reduction in FRC is from both remaining activity of expiratory transverse abdominal muscles, which reduces thoracic volume, and cephalad motion of diaphragm. Paradoxical rib cage motion develops in some subjects during halothane anesthesia, such that the rib cage continues to expand during the first portion of expiration. Such paradoxical rib cage motion is exaggerated during a CO_2-stimulated rebreathing.[218,220]

EFFECTS OF INHALED ANESTHETICS ON THE UPPER AIRWAY

Inspiratory upper airway patency is maintained by the cortical wakefulness drive, fully preserved chemical chemoreceptor sensitivity and chemodrive transmission, and an optimal reflex feedback from upper airway receptors in the conscious state. These upper airway receptors are activated by the negative pressure and airflow[221,222] that are generated by the inspiratory muscles (e.g., diaphragm, respiratory chest wall muscles). During sleep or volatile anesthesia, the cortical wakefulness drive is absent, and the sensitivity of the chemoreceptors and upper airway receptors is decreased. Thus both phasic and tonic inspiratory excitatory drives to the upper airway muscles are decreased or entirely absent. The loss of tone in the upper airway muscles (genioglossus and other pharyngeal muscles) predisposes individuals with anatomic limitations to upper airway obstruction.[223,224] Even in the presence of subanesthetic concentrations of volatile anesthetics (frequently in immediate postoperative period), the cortical wakefulness drive, the drive from peripheral chemoreceptors, and excitatory inputs from upper airway mechanoreceptors are all significantly impaired. This may lead to partial or even complete upper airway obstruction, a situation that can be further complicated by inhibition of hypoxia-mediated arousal reflexes.[203]

EFFECTS OF INHALED ANESTHETICS ON DEFENSIVE AIRWAY REFLEXES

Humans have very effective protective mechanisms to prevent aspiration by closing glottis and coughing. Volatile anesthetics (≥1-1.3 MAC) progressively abolish defensive airway reflexes. The loss of airway protection against gastroesophageal reflux with consequent aspiration of orogastric content into the trachea can be catastrophic. However, lower concentrations of volatile anesthetics may paradoxically enhance and prolong the duration of protective defensive reflexes. Laryngospasm is the sustained and complete reflex glottic closure in response to foreign material (e.g., oral secretions) contacting the vocal cords, or to a poorly timed noxious stimulus (e.g., pain from incision, venipuncture) during the administration of inadequately low concentrations of a volatile anesthetic. This occurs during induction before anesthesia reaches adequate depth and during emergence when the agent is washing out but not completely eliminated. A recent study also showed that laryngospasm could still be observed in 18% of children under deep anesthesia with sevoflurane, but higher concentration (4.7% = MAC_{ED95} intubation) provided better protection from laryngospasm as compared with lower concentration (2.5% = 1 MAC).[225]

Not all volatile anesthetics are equally prone to elicit unwanted sustained defensive airway reflexes. Desflurane and isoflurane appear to be the most irritating to the airways; neither anesthetic is recommended for an inhaled induction of anesthesia. The maintenance and emergence from desflurane anesthesia caused more severe adverse airway events than did isoflurane anesthesia in spontaneously breathing infants and children with an LMA, especially when the LMA was removed before emergence.[226] Sevoflurane has the most favorable profile and is frequently used for inhalational induction in the pediatric population.

INHALED ANESTHETICS AND ACUTE LUNG INJURY

Pathophysiology of Sepsis-Induced Acute Lung Injury

ALI represents the pulmonary manifestation of a global inflammatory process that is commonly associated with gram-negative bacterial sepsis.[227-230] Derangements of pulmonary hemodynamics,[231] fluid filtration, and gas exchange are pathophysiological manifestations.[232] Bacterial endotoxin often triggers ALI.[233] In addition, other humoral and cellular cascades are involved, such as eicosanoids,[234] cytokines, O_2 free radicals, endothelin,[235] NO, as well as the coagulation, the NOTNOT complement,[236] the fibrinolytic, and the kinin/kallikrein systems,[237] as well as degradation fragments of NOT extracellular matrix.[238]

It is now well established that NO is involved in the pathogenesis of sepsis and sepsis-induced ALI. In hyperdynamic sepsis, increased iNOS-dependent formation of NO and, subsequently, cGMP is associated with myocardial depression, reduced contractile responses to vasoconstrictor agents, and circulatory shock.[239] In addition, NO may mediate cytotoxic effects following its reaction with the superoxide anion to yield the strong oxidant anion peroxynitrite and eventually its breakdown cytotoxic product OH•.[240] Large amounts of NO may also activate enzymes in the cyclooxygenase pathway and modify gene expression.[241] Interaction of NO with many molecular targets represents a pathway for its breakdown and inactivation. The most important is the reaction of NO with molecular O_2 to form nitrite, which in the presence of hemoproteins (i.e., hemoglobin) is oxidized further to nitrate.[242]

Moreover, NO may attenuate HPV, thereby contributing to derangement of gas exchange.[243] The latter changes may cause tissue hypoxia and microvascular damage that may result in multiple organ failure and death. However, in less extreme conditions, generation of minute amounts of NO by eNOS and/or iNOS might be protective. Vasodilatation may enhance tissue perfusion. NO inhibition of platelet adhesion and aggregation may produce antithrombotic effects. NO scavenging of superoxide anions and other free radicals and inhibition of leukocyte-endothelial cell adhesion may prevent crucial steps in the inflammatory reactions. Finally, stimulation of cGMP production may preserve the integrity of the microvascular barrier.[244,245]

EFFECTS OF INHALED ANESTHETICS ON EXPERIMENTAL SEPSIS-INDUCED ACUTE LUNG INJURY

There is a substantial debate surrounding the choice of anesthetic regimens for patients with ALI that require surgery. Animal studies suggest an important antiinflammatory role of volatile anesthetics in ALI. Pretreatment with sevoflurane significantly reduced the inflammatory response and attenuated LPS-induced chemotaxis of neutrophils from alveolar type II cells.[246] Compared with thiopental anesthesia, pigs anesthetized with sevoflurane exhibited decreased expression of TNFα and IL-1β in lung tissue.[247] Volatile anesthetics exert other antiinflammatory effects including reduction of proinflammatory cytokine production in alveolar type II cells, reduction of neutrophil migration into the lung interstitium and alveolar space, and decreased protein leakage and pulmonary edema.[248-250] In a rat model, LPS-induced ALI was markedly attenuated by sevoflurane compared with propofol anesthesia. Rats receiving sevoflurane demonstrated improved gas exchange, reduced amounts of albumin and total cell count in bronchoalveolar lavage fluid, and lower cytokine levels in bronchoalveolar lavage fluid and RNA levels in lung tissue compared with rats receiving propofol. Sevoflurane, but not propofol, also decreased the amount of pulmonary edema most likely through a reduction in edema formation rather than water reabsorption.[249] When administered after the onset of oleic acid–induced ALI in dogs, sevoflurane reduced the elevated PA pressure and PVR, attenuated pulmonary edema as evidenced by reduced extravascular lung water index, and decreased TNFα production and diffuse alveolar damage score compared with propofol. However, despite of these effects, sevoflurane worsened systemic oxygenation possibly via inhibition of HPV.[251] In a rat model of cecal ligation and puncture (CLP)–induced sepsis, both sevoflurane and isoflurane attenuated inflammatory response, lipid peroxidation, oxidative stress, and improved survival. Furthermore, sevoflurane was more effective in modulating sepsis-induced inflammatory response.[252] Induction of heme oxygenase-1 and suppression of iNOS expression provide cytoprotection in lung and vascular injury. In a rat model of ALI induced by CLP, the isoflurane posttreatment reduced pulmonary microvascular permeability, as well as lung injury as assessed by histological and immunohistochemical examinations. Furthermore, isoflurane decreased iNOS and increased heme oxygenase-1 expression in lung tissue. These findings suggest that the protective role of isoflurane postconditioning against CLP-induced ALI may be associated with its role in upregulating heme oxygenase-1.[253]

INHALED ANESTHETICS AND VENTILATOR-INDUCED LUNG INJURY

Mechanical ventilation is a life-saving clinical treatment, but it can also produce pulmonary inflammatory changes and injury known as ventilator-induced lung injury (VILI). Cyclic stretching of the lung during mechanical ventilation releases proinflammatory cytokines such as IL-1 and MIP-2 leading to pulmonary neutrophil accumulation; enhances activity of phospholipase A_2, which degrades surfactant; and results in pulmonary edema, hyaline membrane formation, and cellular infiltration.[254] Volatile anesthetics have been shown to attenuate lung injury due to mechanical ventilation. In mice, mechanical ventilation led to induction of lung injury, reactive O_2 species production, proinflammatory cytokine release, and neutrophil influx. Sevoflurane posttreatment reduced histological signs of VILI, as well as prevented increased production of reactive O_2 species, release of IL-1β and MIP-1β, and neutrophil transmigration.[255] Similarly, isoflurane reduced VILI in mice, as indicated by reduced inflammation, transmigration of neutrophils, and cytokine levels. Phosphorylation of Akt protein was significantly increased during mechanical ventilation with isoflurane. Inhibition of phosphoinositide 3-kinase/Akt signaling before mechanical ventilation completely reversed the lung-protective effects of isoflurane. These findings suggest that isoflurane-mediated pulmonary protection is mediated via phosphoinositide 3-kinase/Akt signaling.[256] Moreover, in a murine two-hit model of LPS-induced inflammation followed by VILI, isoflurane exposure before initiation of mechanical ventilation ameliorated VILI by improving both lung mechanics and vascular leakage. In addition, isoflurane prevented a decrease of a key tight junction protein (zona occludens 1) in lung tissue and lung epithelial cells.[257] In another study in murine VILI, animals anesthetized with isoflurane and sevoflurane showed thinner alveolar septa, lower VILI scores, lower polymorph neutrophil counts, lower IL-1β concentrations, less reactive O_2 species production, and higher glutathione contents compared to ketamine-anesthetized mice. Unexpectedly, desflurane-ventilated mice showed signs of lung injury similar to mice receiving ketamine anesthesia. Desflurane also failed to inhibit inflammatory responses and reactive O_2 species production in lung tissue.[258]

INHALED ANESTHETICS AND LUNG ISCHEMIA-REPERFUSION

Lung ischemia-reperfusion (IR) injury is a hallmark of many lung diseases, and it also occurs during surgical procedures such as lung transplantation. The re-establishment of blood flow and O_2 delivery into the previously ischemic lung exacerbates the ischemic injury and leads to increased microvascular permeability and PVR as well as activation of the immune response. These events trigger ALI with subsequent edema formation that can result in systemic hypoxemia and multiorgan failure. Reactive O_2 and nitrogen species have been suggested as crucial mediators of such responses during IR in the lung.[259] Isoflurane attenuated increases in PVR and the filtration coefficient and the wet-to-dry ratio in isolated rabbit lungs subjected to IR.[260] Isoflurane also protected against warm IR injury in an isolated, perfused rat lung model when it was administered after the onset of ischemia.[261] Moreover, reductions in inflammatory responses and oxidative stress were observed during sevoflurane compared with propofol anesthesia in a porcine model of IR injury.[262] In a rat lung transplantation model, preconditioning and postconditioning using sevoflurane significantly improved the oxygenation of lung grafts and decreased pulmonary edema. Sevoflurane treatment also reduced levels of

IL-1β, IL-6, and TNFα. In addition, sevoflurane significantly inhibited cell apoptosis by a decrease in cytochrome C release into cytosol and caspase-3 cleavage.[263] In contrast, pretreatment with desflurane exacerbated IR injury in isolated rabbit lungs perfused with saline by increasing pulmonary microvascular permeability and NO production.[264] Furthermore, postconditioning with xenon during prolonged ex vivo lung perfusion did not improve graft function in a porcine warm ischemic lung injury model.[265]

CLINICAL EVIDENCE

Clinical evidence supports potential beneficial effects of volatile anesthetics in ALI. For example, short-term positive pressure ventilation with high tidal volumes did not affect cytokine production in the lungs of healthy patients anesthetized with isoflurane.[266] Several studies investigated the effects of volatile anesthetics in patients undergoing thoracic surgery with OLV.[267-269] OLV is associated with hypoxia-reoxygenation injury in the deflated and subsequently reventilated lung. OLV increased the release of proinflammatory mediators in both the dependent and the nondependent lung.[268] Sevoflurane suppressed local alveolar inflammatory responses and cytokine release compared with propofol. Furthermore, the antiinflammatory effects of sevoflurane were greater in the dependent compared with the nondependent lung.[268,269] Patients receiving sevoflurane also had an improved postoperative course as indicated by a shorter ICU stay and fewer adverse events including pneumonia, pleural effusion, and bronchopleural fistula compared with those anesthetized with propofol.[267] In addition, a recent meta-analysis in cardiac surgical patients demonstrated that volatile as opposed to intravenous anesthesia is associated with a significant reduction in pulmonary complications and overall mortality.[270] However, in a randomized multicenter controlled trial in patients scheduled for surgery with OLV, the incidence of major complications during hospitalization and within 6 months from surgery was similar in propofol and desflurane groups.[271] This finding seems to be in agreement with an earlier study demonstrating that in healthy surgical patients desflurane increased lipid peroxidation as measured in BALF, indicating injury to the pulmonary alveolar membranes. Sevoflurane caused less pronounced effects, suggesting that it may exert a protective effect compared with desflurane.[272] Proinflammatory response and elevated levels of TNFα, IL-1β, and IL-6 in healthy patients undergoing tympanoplasty were also more evident following desflurane anesthesia compared with sevoflurane.[273]

In a recent parallel, open-label, single-center randomized controlled trial, adult patients with moderate-to-severe ARDS were randomized to receive either intravenous midazolam or inhaled sevoflurane for 48 hours. On day 2, PaO_2/FiO_2 ratio was significantly higher in the sevoflurane group than in the midazolam group. There was also a significant reduction in cytokines and the soluble form of the receptor for advanced glycation end-product levels in the sevoflurane group, compared with the midazolam group. No serious adverse events were observed with sevoflurane. This study suggests therapeutic utility of inhaled sevoflurane in patients with ARDS.[274] Moreover, the use of inhaled anesthetics in the ICU is conceptually appealing as they offer a safe, effective, and easily titratable method of sedation. A recent retrospective analysis of patients receiving inhaled sedation in the ICU suggests an association between its use and reductions in one-year and in-hospital mortality, perhaps related to a significant increase in ventilator-free days compared to sedation with intravenous agents.[275] Prospective randomized clinical trials are needed to further elucidate the therapeutic potential of inhaled anesthetics in intubated patients with ALI/ARDS and ICU patients requiring long term sedation.

Nonvolatile Inhaled Agents

The pharmacokinetics of all inhalational anesthetics follow the same principle. At initial uptake, the dynamic change of the ratio of the fraction of a gas in alveoli (FA) to its fraction in the inspiratory gas (FI) (FA/FI) is dependent on initial FI, solubility of the anesthetic, minute alveolar ventilation, and cardiac output. Fig. 21.21

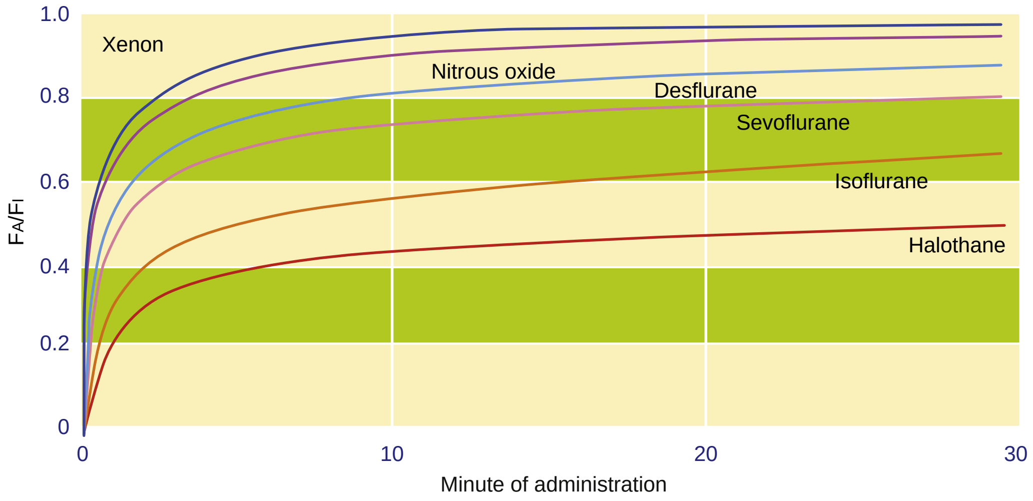

Fig. 21.21 Pharmacokinetics of the inhalational anesthetics. The rise in alveolar (FA) anesthetic concentration towards inspired (FI) is most rapid with the least soluble anesthetic, N2O, and slowest with the most soluble, methoxyflurane. All data from human studies (Data from Yashuda N, Lockhart SH, Eger EI II, et al. Kinetics of desflurane, isoflurane and halothane in humans. Anesthesiology 74:489-498, 1991; & Anesth Analg 72:316-24, 1991; Data for Xenon only recently available.

demonstrates the dynamic changes in FA/FI of inhalational anesthetics during the phase of uptake. Because xenon has the lowest solubility among the all inhalational anesthetics, it reaches equilibrium quickly, and even faster than nitrous oxide. The speed of washout of anesthetics also follows the same principle but in the reverse direction. Among the four factors affecting washout (solubility, fresh gas flow rate, minute alveolar ventilation, and cardiac output), fresh gas flow is the only one the provider can fully control besides partially controlling minute alveolar ventilation. Adequate fresh gas flow plays an important role in preventing rebreathing expired gas and affects the rate of its elimination. Fresh gas flow has to be higher than the peak inspiratory flow rate for the adult breathing circuit. If a tidal volume is 500 mL, respiratory rate is 10, and I:E ratio is 1:2, the inspiratory phase is 4 seconds. The mean inspiratory flow rate is 500 mL/4 seconds, 125 mL/s, or 7500 mL/min. Therefore maximal O_2 flow rate of 10 to 15 L/min for any given modern ventilator should be large enough to prevent rebreathing expired gas. For circuits used in pediatric patients, the minimal fresh gas flow rate for preventing rebreathing is dependent on the type of the circuit. In the following section, two commonly used nonvolatile gases, xenon and nitrous oxide, are discussed with focus on their clinically related aspects.

NITROUS OXIDE

Advantages of nitrous oxide (N_2O) are well established including the ability to quickly reach its target MAC value and quick washout. N_2O does not significantly interfere with respiratory drive and has no negative impact on bronchial mucosa or bronchial smooth muscle activity in healthy individuals. N_2O enhances catecholamine release and does not reduce systemic vascular resistance or cardiac output, maintaining hemodynamic stability. Because its MAC value is 104%, N_2O cannot be used as a sole anesthetic at 1 atmosphere pressure to achieve adequate sedation. However, because it is odorless, it is often used as an adjuvant at the beginning of inhalational induction, especially in pediatric patients, prior to administration of volatile anesthetics. It is also commonly used for analgesia and sedation for dental procedures.[276] Its use for labor pain has faded but it is still used for labor analgesia in some centers.[277]

Sedative and Analgesic Effects

Nitrous oxide has both sedative and analgesic effects. Because MAC is determined as the threshold of an individual's response to the painful stimulation of skin incision, and N_2O is analgesic, it is difficult to dissect its sedative from analgesic effects. Therefore the sedative potency of N_2O at equal MAC values is different from other inhalational anesthetics which do not possess analgesic effects. The MAC of N_2O and other inhalational anesthetics are additive relative to a subjects' movement in response to nociceptive stimulation, but not necessarily when it comes to the level of sedation. For most volatile anesthetics, MAC awake is approximately 0.3 MAC value.[278] However, the MAC awake of N_2O is 0.61 MAC (63.3%).[278] Even at 50% of N_2O or 0.48 MAC, the majority of adults may be conscious. Clinicians often use N_2O at the end anesthesia in order to facilitate washout of a volatile anesthetic. Even though the sum of the MAC values of the volatile anesthetic and that of N_2O is above the MAC awake value of the volatile anesthetic alone, this does not guarantee the unconsciousness of the patient. Awareness may occur even though it may not be associated with postoperative recall.[279]

In humans, the analgesic effect of 66% to 70% of N_2O is equal to that of an intravenous infusion of remifentanil at 0.085 to 0.17 mg/kg/min, or a whole-blood concentration of 2 ng/mL.[280,281] Analgesic potency of N_2O can be attenuated by sevoflurane (Fig. 21.22).[282] The detailed pathway of its analgesic action remains to be determined. However, animals tolerant to N_2O are cross-tolerant to morphine,[283] and the analgesic effect of N_2O can be reversed by naloxone.[284] This means that at least in part, the analgesic action of N_2O occurs via the mu opioid receptor. Small animals develop tolerance quickly (6-24 hours) following continuous administration of N_2O.[284] Humans can also develop acute tolerance to N_2O in only 40 minutes.[285] In clinical practice, N_2O is commonly administered for several hours. However, it is to be determined whether its sedative and/or analgesic effects remain during prolonged administration.

Gas Volume Expansion

Nitrous oxide has greater diffusibility across tissues than nitrogen. Therefore N_2O would diffuse into any closed air-containing space, more specifically any nitrogen-containing space, more quickly than nitrogen diffuses out, resulting in gas volume expansion. One of the major concerns related to this gas expansion effect is bowel dilatation.[286] However, this observation is based on surgical procedures lasting 3 hours. The increase in pressure and volume in a closed space due to accumulation of N_2O is dependent of the duration of exposure and pressure

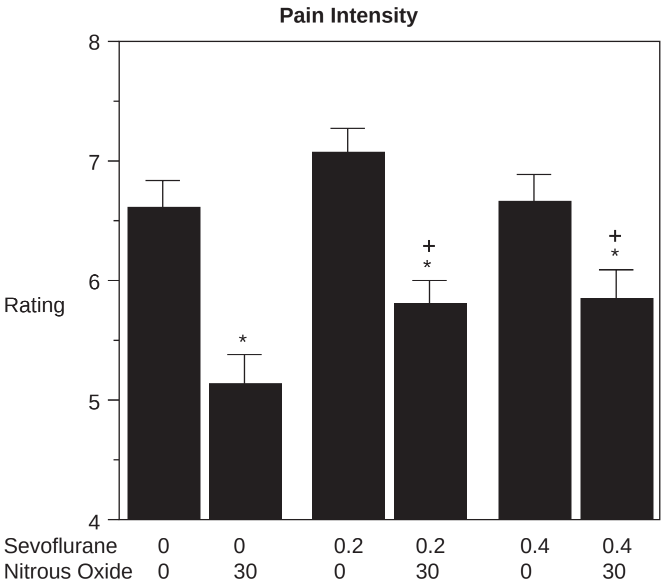

Fig. 21.22 Effects of sevoflurane and nitrous oxide on ratings of pain intensity to cold. Each bar is the mean across all subjects. *Brackets* represent SEM. *Significant decrease from placebo (0% sevoflurane/0% nitrous oxide) ratings. $^+$Significant increase from the 0% sevoflurane/30% nitrous oxide ratings. (Redrawn from Janiszewski DJ, Galinkin JL, Klock PA, et al. The effects of subanesthetic concentrations of sevoflurane and nitrous oxide, alone and in combination, on analgesia, mood, and psychomotor performance in healthy volunteers. *Anesth Analg.* 1999;88(5):1149-1154. With permission.)

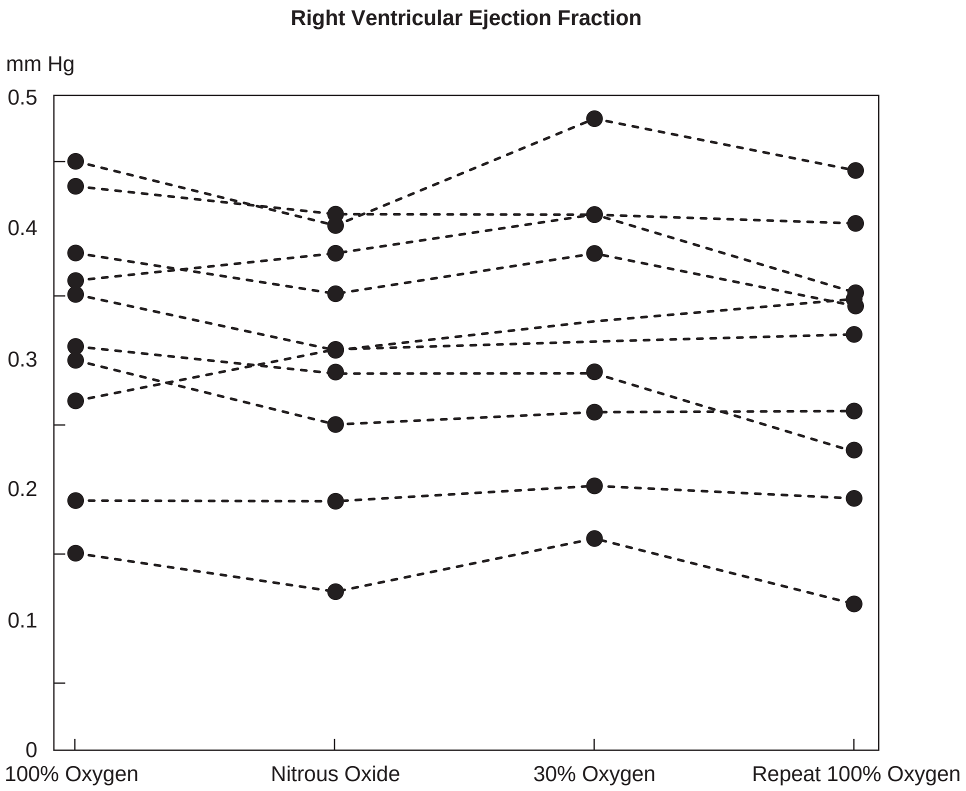

Fig. 21.23 Individual patient responses in mean pulmonary arterial pressure (mm Hg) to nitrous oxide administration. (Redrawn from Konstadt SN, Reich DL, Thys DM. Nitrous oxide does not exacerbate pulmonary hypertension or ventricular dysfunction in patients with mitral valvular disease. *Can J Anaesth.* 1990;37(6):613-617. With permission.)

gradient of N_2O. Briefly using N_2O for periods of 15 to 20 minutes during emergence enhances washout of volatile anesthetics and may not lead to clinically relevant bowel dilation.

Nausea And Vomiting

Postoperative nausea and vomiting (PONV) is a common complication of N_2O.[287] However, a recent meta-analysis demonstrated that N_2O–related PONV is clinically insignificant following a less than 1 hour exposure.[288] The authors suggested that a minor risk of PONV should not preclude N_2O use for a limited time period, such as for minor or ambulatory surgeries. Even though others questioned the methodology of the meta-analysis,[289,290] the trend consistently suggests that the incidence of PONV is associated primarily with the *duration* of N_2O exposure. Therefore clinicians can take advantage of the beneficial properties of N_2O, especially at the end of an anesthetic, to facilitate the washout of volatile agents and shorten the time of emergence.

Pulmonary Hypertension

Several studies were conducted to test whether N_2O worsens pulmonary hypertension with no consistent conclusions due to variation of the experimental protocols. In an earlier study, Konstadt and colleagues demonstrated no significant changes in PA pressure and cardiac output in patients with pulmonary hypertension when 70% N_2O versus 70% nitrogen was used (Fig. 21.23).[291] The authors concluded that N_2O does not have adverse effects on the pulmonary circulation or right ventricular function, and may be used with appropriate monitoring in patients with pulmonary hypertension. This conclusion should be interpreted with caution in patients with elevated PVR, particularly in the presence of right ventricular dysfunction and/or right coronary artery disease.[292] More recently, the ENIGMA II study, a large randomized clinical trial, demonstrated no difference in the risk of death or cardiovascular complications with N_2O.[293]

Potential Neurotoxicity of Nitrous Oxide

Prolonged use of N_2O can cause nitrous oxide–induced blockade of N-methyl-D-aspartate (NMDA) receptors and can manifest as swelling of neuronal organelles including mitochondria and endoplasmic reticulum,[294] presenting as neurotoxicity[295] with an acute neuropathy postoperatively.[296] Nitrous oxide also increases plasma homocysteine levels[297] caused by oxidation of methionine synthase.[298] As homocysteine can be easily measured in blood, it can be used as a biomarker of N_2O-induced modulation of methionine synthase activity. After an 8-hour exposure to N_2O, an eight-fold increase in blood homocysteine levels was detected.[299] Increased homocysteine may be prevented by continuous infusion of vitamin B_{12}, which is an enzyme cofactor of methionine synthase.[300]

XENON

Xenon has been suggested as an ideal inhalational anesthetic. It is stable, nonbiotransformable, nontoxic, nonflammable, nonirritant, and has a low blood–gas partition coefficient. Because of its specific molecular properties, xenon (Xe^{129}) can be hyperpolarized, with ventilation

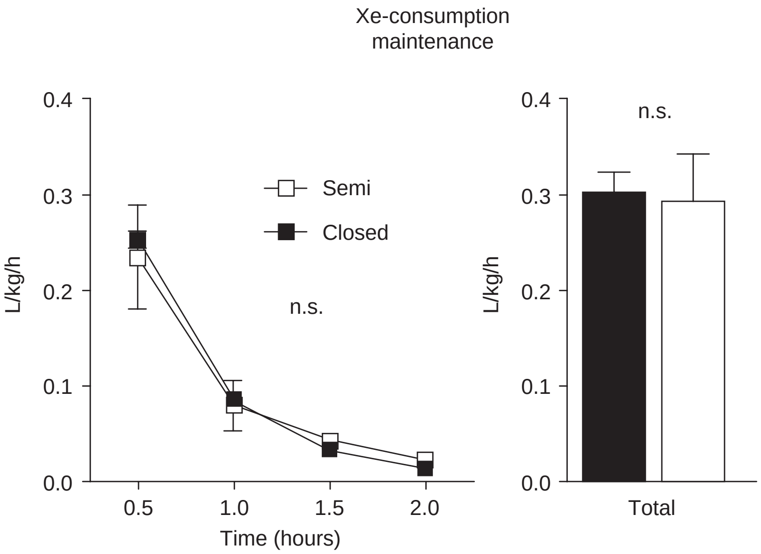

Fig. 21.24 Xenon consumption during the maintenance phase in a semi-closed and closed circuit, shown for 30 minute intervals and in total for 2 hours. ***n.s.*, not significant.** (Redrawn from Roehl AB, Goetzenich A, Rossaint R, et al. A practical rule for optimal flows for xenon anaesthesia in a semi-closed anaesthesia circuit. *Eur J Anaesthesiol.* 2010;27(7), 660–665. With permission.)

distribution and gas uptake yielding a highly selective tool for 3D MRI evaluation of lung disease.[301] Therefore xenon is used more frequently as an agent for imaging rather than as an inhalational anesthetic. However, its sedative effect is unique and mainly conferred by the inhibition of NMDA receptors in the central nervous system. In 1969, Cullen and colleagues determined the MAC of xenon to be 71% in O_2.[302] Using more modern measurements, Nakata and colleagues determined the MAC to be 63.1%.[303] A recent meta-analysis concluded that xenon anesthesia provides more stable intraoperative blood pressure, lower heart rate, and faster emergence from anesthesia than volatile agents and propofol, but xenon is associated with a higher risk of PONV (Fig. 21.24).[304]

Speed of Emergence and Postoperative Cognitive Dysfunction with Xenon

Compared with volatile anesthetics and propofol, anesthetic emergence is faster with xenon. It shortens time to extubation by approximately 4 minutes.[304] However, the shortening of emergence is not associated with the reduction in length of PACU or hospital stays. There is some evidence suggesting that, compared with other general anesthetic agents, xenon is associated with better neurological outcomes.[305] Therefore it might reduce the occurrence of postoperative cognitive dysfunction. A recent study did show that compared with sevoflurane, xenon was associated with faster emergence and with better early postoperative cognitive recovery.[306] However, such a benefit did not extend beyond 2 to 3 days post operation.[307] Xenon did not show benefits in postoperative cognitive dysfunction in elderly patients compared with desflurane[308] or propofol.[309] Therefore its neuro-protective potential remains debatable for patients undergoing general anesthesia.

Intraoperative Hemodynamics and Postoperative Outcome

Multiple studies have demonstrated that xenon produces a more stable intraoperative hemodynamic response. Xenon is a sympathetic stimulant and better maintains systolic, diastolic, and mean arterial blood pressures and reduces heart rate.[310] Such a favorable hemodynamic profile is very unique and beneficial in contrast to most volatile anesthetics that reduce systemic vascular resistance and perfusion pressure and increase heart rate. Hofland and colleagues recently demonstrated that compared with total intravenous anesthesia or anesthesia with sevoflurane, xenon reduces postoperative cardiac troponin I release and was noninferior to sevoflurane in low-risk, on-pump coronary artery bypass graft surgery patients.[311] However, the benefit of xenon as a cellular protectant observed in vitro[312] has not yet been demonstrated in human studies.

Use of Xenon in Critical Care

Sedation in the ICU usually lasts much longer than it does in anesthesia. Xenon could potentially be an ideal agent for sedation in the critical care setting, provided that its neuroprotective effect demonstrated in preclinical studies will be confirmed in humans.[313] However, there is currently a lack of clinical trials to determine the outcome of sedation with xenon compared to conventional sedation regimens in the ICU. A recent study by Bedi and colleagues[314] demonstrated the safety and feasibility of its use in critical care. Compared with a conventional propofol sedation regimen, similar sedation can be achieved at xenon concentrations of 28 ± 9.0% (range 9%-62%).[315]

Postoperative Nausea and Vomiting

Xenon is a potent antagonist at the 5-HT3 receptor,[316] and could theoretically exert intrinsic antiemetic properties. However, a previous study demonstrated that xenon causes an increase in risk of PONV by 72% (34.4% vs. 19.9%) when compared with volatile and propofol anesthesia.[304] In contrast, Schaefer and colleagues recently assessed the risk of nausea and vomiting among several anesthetic regimens and concluded that xenon causes nausea and vomiting no more frequently than other regimens.[317]

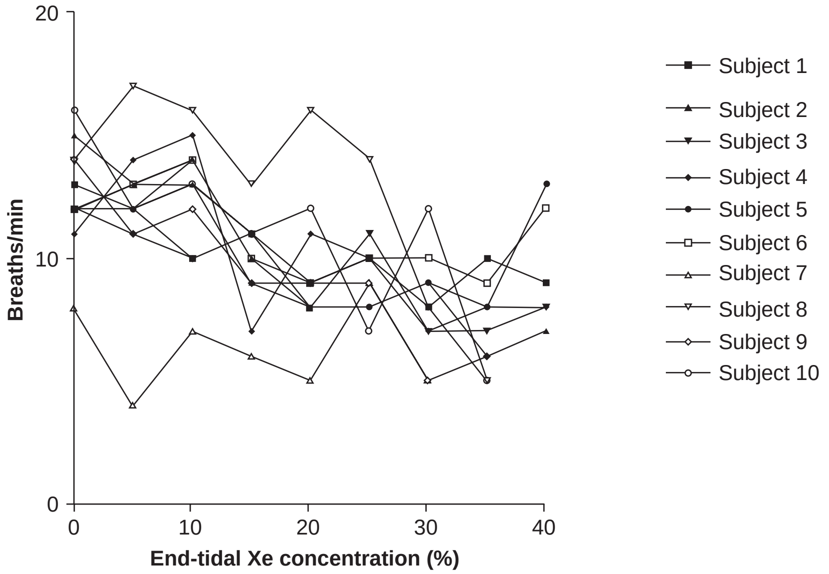

Fig. 21.25 The respiratory rate (breath/min) for individual subjects at increasing end-tidal concentration of xenon in oxygen. (Redrawn from Bedi A, McCarroll C, Murray JM, et al. The effects of subanaesthetic concentrations of xenon in volunteers. *Anaesthesia*. 2002;57(3):233–241. With permission.)

Airway Resistance

Xenon has a high density and viscosity. Therefore when using xenon, airway resistance is greater compared to other inhalational anesthetics at equivalent MAC values. The increase in airway resistance with 70% xenon mixed with 30% O_2 compared to 70% nitrogen mixed with 30% O_2 was minimal in healthy lungs in a pig model. However, the airway resistance was further increased in a bronchoconstriction model of asthma. Increased airway resistance is an intrinsic property of xenon and probably not a result of bronchoconstriction. The increase in airway resistance does not negatively affect oxygenation[318] and is not associated with decreased airway diameter.[319] Similar results were also reached in a dog model.[320] A human study with 33% xenon and 67% O_2 showed a significant increase in airway pressure but no alteration in oxygenation was reported.[321]

Apnea

Xenon is the only inhalational anesthetic that causes a decrease in respiratory rate(Fig. 21.25).[187] There are a few case reports describing prolonged apnea occurring in spontaneously breathing patients, even with subanesthetic concentrations of xenon.[188]

TABLE 21.2 Comparison of Xenon and Nitrous Oxide

	Nitrous oxide	Xenon
Pharmacodynamics	Comparable	Comparable
Sedation mechanism	NMDA	NMDA
Analgesic effect	Yes	Yes
Gas expansion	Yes	No
Nausea and vomiting	Yes	Yes
Increase in airway resistance	No	Yes
Increase in pulmonary vasculature resistance	Maybe	No
Diffusion hypoxia	Yes	No
MAC value	104%	63.1%-71%
MAC awake	63.3%	32.6%
Use as a sole anesthetic at ambient pressure at sea level	No	Yes
Respiratory rate	No effect	Decrease
Maintain hemodynamic stability	Yes	Yes
Acute tolerance	Yes	Unknown
Cost-efficiency	Favorable	Not favorable at present

MAC, Minimum alveolar concentration; *NMDA,* N-methyl-D-aspartate.

COMPARISON OF NITROUS OXIDE AND XENON

Both N_2O and xenon are nonvolatile inhaled anesthetics. Their pharmacodynamics are similar, although the solubility of N_2O is higher than that of xenon. The site of action of xenon[322,323] and N_2O[324,325] are believed to be the same: the NMDA receptor. However, imaging studies show that xenon and N_2O do not work on the same regions of the brain.[326,327] In addition, their sedative[328] and analgesic[329,330] properties, and their side effects[331,332] are not the same. Recently, concern has been raised for air pollution associated with the use of N_2O, and whether it should be routinely used in anesthesia. Since N_2O has not been shown to be associated with an increased rate of wound infections and its cost-effectiveness is favorable, there is no evidence to support abandoning N_2O for routine inhalational anesthetic use. On the other hand, since the superiority of xenon over the volatile anesthetics and N_2O remains to be determined and its cost is high, routine use of xenon as anesthetic is not recommended(Table 21.2).[333-335]

Summary

Even though the popularity of total intravenous anesthesia has been growing over the last two decades, inhalational anesthetics remain the most commonly used agents for general anesthesia. At least in part, this is due to our current thorough understanding of the pharmacology of these agents and their cost-efficiency. Measurement of the expiratory gas concentrations is readily available in any modern anesthesia machine and therefore the depth of sedation is much easier to determine and monitor, compared with intravenous anesthesia. Thus inhalational anesthesia will remain in the mainstream of anesthesia practice for the foreseeable future. Careful selection of a particular agent based on the mechanism of its action can improve quality of patient care. Such care will continue to be based on an individual's needs, with consideration of the pharmacokinetics and interactions of these agents with the respiratory system. Further research into the clinical utility of the inhalational agents is essential for advancing the goals of precision medicine in anesthesia.

Acknowledgment

This chapter is a consolidation of two chapters in the eighth edition, Chapter 27 Inhaled Anesthetics: Pulmonary Pharmacology and Chapter 28 Inhaled Anesthetics: Cardiovascular Pharmacology. The editors and publisher would like to thank the following authors: Neil E. Farber, Eckehard A.E. Stuth, Astrid G. Stucke, and Paul S. Pagel for their contributions to the prior edition of this work. It has served as the foundation for the current chapter.

Inhaled Anesthetics: Delivery Systems

MICHAEL P. BOKOCH and STEPHEN D. WESTON

KEY POINTS

- The modern anesthesia workstation has evolved into a complex device with a number of safety features. However, if there is any possibility that the workstation or the breathing circuit is a potential cause of difficulty with ventilation or oxygenation, ventilating the patient using an oxygen cylinder and a manual ventilation bag is an appropriate decision. *When in doubt, ventilate and oxygenate the patient first via another method—troubleshoot later.*
- The most important part of the preanesthesia workstation checkout procedure is to verify the presence of a self-inflating resuscitation bag and that an alternative oxygen source (E-cylinder) is available.
- The Diameter Index Safety System (DISS) is designed to prevent the misconnection of hospital gas supply lines to the anesthesia workstation. The Pin Index Safety System (PISS) is designed to prevent incorrect gas cylinder connections in the anesthesia workstation. Quick coupling systems may be utilized to connect to the central gas supply. No system is immune to misconnection.
- In the event of hospital pipeline crossover or contamination, two actions must be taken: the backup oxygen cylinder valve must be opened, and the wall supply sources must be disconnected. Otherwise, the suspect hospital pipeline gas will continue to flow to the patient.
- The oxygen flush valve provides a high flow of 100% oxygen directly to the patient's breathing circuit, allowing the anesthesia provider to overcome circuit leaks or to rapidly increase inspired oxygen concentration. Improper use can be associated with barotrauma or patient awareness.
- When using nitrous oxide, there is a risk of delivering a hypoxic mixture to the patient. "Fail-safe" valves and nitrous oxide/oxygen proportioning systems help minimize this risk, but they are not truly fail-safe. Delivery of a hypoxic mixture to the fresh gas outlet can result from (1) the wrong supply gas, (2) a defective or broken safety device, (3) leaks downstream from these safety devices, (4) administration of a fourth inert gas (e.g., helium), and (5) dilution of the inspired oxygen concentration by high concentrations of inhaled anesthetic agents (e.g., desflurane).
- The low-pressure section (LPS) of the gas supply system includes the flow control valves, flowmeters or flow sensors, and the anesthetic vaporizers. This section of the anesthesia workstation is most vulnerable to leaks, which can cause delivery of a hypoxic gas mixture or an inadequate concentration of anesthetic agent to the patient. The workstation must be checked for leaks before delivery of an anesthetic.
- The oxygen analyzer is the only protection against a hypoxic mixture within the low-pressure section of the pneumatic system.
- Anesthesia workstations with a one-way check valve in the LPS require a manual negative-pressure leak test. On machines without a check valve in this location, manual positive-pressure testing or automated testing is used to test the LPS for leaks.
- On machines with manually controlled anesthetic vaporizers, internal vaporizer leaks can be detected only when the vaporizer is turned on. This is true even during automated machine self-tests. Machines with electronically controlled vaporizers (e.g., the GE/Datex-Ohmeda Aladin cassette vaporizer, Maquet FLOW-i anesthesia workstation vaporizer) can check the installed vaporizer during self-test.
- Variable bypass vaporizers route a portion of the fresh gas flow into a vaporizing chamber to create the desired anesthetic concentration. Injection-type vaporizers utilize microprocessor control to inject small amounts of anesthetic liquid into an evaporating chamber.
- Desflurane's low boiling point and high vapor pressure make it unsuitable for a variable bypass vaporizer. Misfilling a variable bypass vaporizer with desflurane could theoretically cause delivery of a hypoxic mixture and a massive overdose of inhaled desflurane.
- The major advantage of the *circle breathing system* is the capability to rebreathe exhaled gas, including volatile anesthetic. The major disadvantage is its complex design with multiple connections.
- Before an anesthetic agent is administered, the circle system must be checked both to rule out *leaks* and to verify *flow*. To test for leaks, a static test is performed: the circle system is pressurized and the airway pressure gauge is observed not to fall. An automated test may perform this

function on many modern machines. To rule out obstruction or faulty valves, a dynamic test is performed, ventilating a test lung (usually a breathing bag) using the anesthesia workstation's ventilator, and observing for appropriate "lung" motion.

- Increasing the fresh gas flow rate into the circle breathing system causes less rebreathing of volatile anesthetic gas and more waste gas. To avoid rebreathing of carbon dioxide, a carbon dioxide absorbent is essential to the circle system's function.
- Inhaled anesthetic agents can interact with carbon dioxide absorbents and produce potentially harmful degradation products. Sevoflurane can form compound A, especially at low fresh gas flows. Several volatile anesthetics, though especially desflurane, can lead to release of carbon monoxide when exposed to desiccated absorbents. Carbon dioxide absorbents without strong bases such as potassium hydroxide or sodium hydroxide decrease this risk.
- The Mapleson breathing circuits are simple, lightweight breathing systems that support both spontaneous and manual ventilation. The particular circuit design has implications on the required fresh gas flow to avoid rebreathing of exhaled gases. None are economical for volatile anesthetic use, as they do not support carbon dioxide absorbent use.
- Anesthesia ventilators differ from intensive care unit ventilators in that they must support the rebreathing of exhaled gases. Types of anesthesia ventilators include bellows, piston, volume reflector, and turbine. Each design has its own benefits and limitations. Contemporary anesthesia ventilators support a wide variety of ventilation modes similar to intensive care unit ventilators.
- For bellows-type anesthesia ventilators, ascending bellows (bellows that ascend during the expiratory phase) are safer than descending bellows (bellows that descend during the expiratory phase) because disconnections are readily manifested by failure of ascending bellows to refill.
- Piston ventilators can potentially draw room air into the breathing circuit if a leak is present. The Maquet FLOW-i volume reflector compensates for leaks with 100% oxygen. Both are susceptible to lower than expected levels of inhaled anesthetic.
- On older anesthesia machines, the portion of fresh gas flow that occurs during inspiration is added to the tidal volume. Therefore increased fresh gas flow leads to increased tidal volume and increased airway pressure during positive-pressure ventilation. Newer-generation anesthesia workstations either *decouple* the fresh gas flow from the inspired tidal volume, or *compensate* for the fresh gas flow in calculating the amount of gas to deliver as tidal volume. Anesthesia providers should know whether their machines compensate for changes in fresh gas flow.
- The anesthesia gas scavenging system protects the operating room from waste anesthesia gases. Active systems, which apply vacuum suction to the scavenge system, are most common in contemporary operating rooms. Obstruction of, or inadequate vacuum to, the scavenging system transfer tubing can result in increased breathing circuit pressure or discharge of waste anesthesia gases to the operating room, depending on design.
- The American Society of Anesthesiologists *Recommendations for Pre-Anesthesia Checkout Procedures (2008)* serves as an excellent template for the creation of machine-specific checkout procedures. However, it is not a one-size-fits-all checklist.

Although the modern anesthesia workstation bears little resemblance to the ether-soaked rags of the mid-1800s, it is at its heart a device for delivering inhaled anesthesia. Early inhaled anesthetics provided no certainty regarding the delivered concentration of anesthetic, relied on spontaneous breathing of room air, possessed little more than the vigilance of the anesthesia provider for safety systems, and exposed the operating room to the anesthetic vapor. The evolution of the anesthesia workstation has provided increasingly sophisticated solutions to each of these problems. Today, anesthesia workstations are designed to do all of the following:

- Deliver volatile anesthetic gas at precise concentrations.
- Individually meter oxygen and two or more other breathing gases, and continuously enrich the inhaled gas with anesthetic vapor.
- Allow the patient to be ventilated manually ("bag" ventilation) with adjustable breathing circuit pressure.
- Ventilate the patient mechanically, with sophisticated ventilator modes comparable to the intensive care unit (ICU).
- Allow rebreathing of the exhaled anesthetic gases after removing carbon dioxide.
- Eliminate ("scavenge") excess gas from the patient's breathing circuit and remove this gas from the room.
- Continuously measure and display the inspired oxygen concentration, as well as ventilatory parameters such as respiratory rate and tidal volume.
- Prevent hypoxic gas mixtures caused by operator error or gas supply failure.
- Provide a breathing circuit manual oxygen flush feature.
- Possess a backup supply of oxygen.
- Display gas pipeline and backup tank supply pressures.
- Provide an integrated platform for displaying anesthetic, hemodynamic, and respiratory parameters, and for collecting this data into an electronic medical record.

The sheer number of tasks and solutions for which the anesthesia workstation is designed explains its complexity. Newcomers to the specialty often find the anesthesia machine to be both mysterious and intimidating, even though they sometimes have had experience with other ventilation equipment, such as ICU ventilators. Understanding the anesthetic workstation is important because the workstation is one of the most essential pieces of equipment used by anesthesia care providers. Nevertheless, it is worth emphasizing that if there is any doubt about the correct functioning of an anesthesia workstation, and there is difficulty with ventilation or oxygenation, then ventilating the patient with an alternative source of oxygen such as an E-cylinder is of top priority. Troubleshooting the anesthesia machine can commence once the patient is safe.

While some of the design and engineering innovations in anesthesia workstations make the anesthesia provider's job easier or more efficient, many of the innovations aim to enhance patients' safety. Closed claims analysis of adverse anesthetic outcomes related to anesthetic gas delivery equipment shows that such claims now account for only approximately 1% of the claims in the American Society of Anesthesiologists (ASA) closed claims database.[1] Further, the severity of the events leading to the claims has tended to decrease compared with closed claims analysis of earlier decades, with more reports of awareness under anesthesia, and fewer reports of death or permanent brain injury.[1,2]

To prevent mishaps, anesthesia providers must be aware of the operational characteristics and functional anatomy of their anesthesia workstations. Many workstations and their components share very similar characteristics, but the variation among them is growing. Similarly, the operational and pre-use checkout procedures are becoming more divergent, thus mandating device-specific familiarity. Unfortunately, a lack of knowledge pertaining to the anesthesia workstation and a lack of understanding and application of a proper pre-use check are common.[3-7] Contemporary machines have automated pre-use checkout procedures, but performance adherence is uneven.[6] More importantly, machines can pass automated checkouts despite the presence of unsafe conditions.[8,9] Safe use requires a solid generic understanding of any anesthesia workstation, as well as machine-specific knowledge of features and checkout procedures.

Providing a detailed description of each gas system, subsystem component, and patient breathing circuit is not practical within the scope of a single chapter. However, because anesthesia workstations must adhere to basic standards, a generic approach to all machines will be presented. Although several subsystems are described in detail in this chapter, anesthesia providers must acquire a functional understanding of their own workstations and ensure that their local pre-use checkout procedures are suitable for their machines. This chapter will review guidelines for anesthesia workstations; functional anatomy including gas supply, vaporizers, breathing circuits, ventilators, and scavenging; and the anesthesia machine pre-use checkout.

Standards and Guidelines for Anesthesia Workstations

Standards for medical devices and anesthesia workstations provide guidelines for manufacturers regarding device minimum performance, design characteristics, and safety requirements. For the anesthesia workstation, many of these requirements are outlined in the standards of the International Organization for Standardization (ISO). The ISO is a developer of international voluntary consensus standards based on global expert opinion, including industry and academia, as well as governments, consumer organizations, and other nongovernmental organizations.[10] The current standards are defined within the *Particular Requirements for Basic Safety and Essential Performance of an Anesthetic Workstation*, ISO 80601-2-13, of 2011.[11] The ISO standards also reference a large number of other components such as: electrical standards, device construction and performance, and even software standards. The relevant standards promulgated by the ASTM International (formerly known as the American Society for Testing and Materials), were withdrawn in 2014 because they had not been updated. Additional key standards for machine subsystems arise from the Compressed Gas Association and the Institute of Electrical and Electronics Engineers.

The ISO standards for the anesthetic workstation—or "anesthesia workstation," or "anesthesia machine," all used interchangeably in this chapter—include standards for numerous aspects of the design and construction of the workstation, including the anesthetic gas delivery system and anesthetic breathing system, as well as for monitoring equipment, alarm systems, and protection devices. The focus of this chapter is on design and functional aspects of the anesthesia workstation relevant to the delivery of inhaled anesthesia.

The ASA publishes several guidelines pertaining to the anesthesia workstation.[11a] The *Recommendations for Pre-Anesthesia Checkout*, which was updated last in 2008, serves as a general guideline for individual departments and practitioners to design checkout procedures specific to their anesthetic delivery systems.[11b] The ASA *Guidelines for Determining Anesthesia Machine Obsolescence* helps assist anesthesia providers and other healthcare personnel, administrators, and regulatory bodies to determine when an anesthesia machine is obsolete by applying both absolute and relative criteria.[11c] Finally, the ASA publishes *Standards for Basic Anesthetic Monitoring*, which outlines minimal monitoring standards pertaining to oxygenation, ventilation, circulation, body temperature, and the requirements for the presence of anesthesia personnel.[11d] Standards and recommendations pertaining to the anesthesia workstation are published by several other international anesthesiology societies.[11e,11f]

the pneumatic system is no longer mediated by a flowmeter, but rather by a touchscreen. However, the interior of the anesthesia machine remains a pneumatic system. It is where breathing gases are delivered from their supply sources, measured, mixed, passed through an anesthetic vaporizer, and delivered to the patient's breathing circuit. The details of this gas supply system may differ between the various manufacturers' anesthesia workstations, but their overall schematic is similar. Fig. 22.1 presents the gas supply system of a more traditional anesthesia machine, without electronic controls. Fig. 22.2 demonstrates a typical contemporary workstation with electronic controls.

The gas supply system consists of the following elements: oxygen, air, and nitrous oxide may enter the anesthesia machine from either the hospital gas pipeline system, or from E-cylinders mounted on the back of the anesthesia machine. The gases flow through pressure regulators to reach flow control valves before reaching flowmeters, anesthetic vaporizers, and the patient's breathing circuit via the fresh gas outlet. There are a number of safety mechanisms in place along this route to avoid delivering a hypoxic gas mixture at the fresh gas outlet. In addition, the system is designed to be able to rapidly fill the patient's breathing circuit with 100% oxygen (oxygen flush valve), and to provide 100% oxygen from a flowmeter; both of these features are active even when the machine is off or without power.

The gas supply system can be divided into three sections: high-pressure, intermediate-pressure, and low-pressure. The only high-pressure elements in the anesthesia machine are the auxiliary gas tanks (E-cylinders) on the back of the anesthesia machine. The pressure in these tanks (approximately 2000 pounds per square inch gauge [psig] for air and oxygen, 745 psig for nitrous oxide) is immediately stepped down to an intermediate pressure. The hospital's gas pipelines are themselves of intermediate pressure (50-55 psig), so the intermediate pressure section starts from the pipelines or from the stepped-down input from the E-cylinders, and extends up to the flowmeter control valves. The low-pressure section begins at the flowmeter control valves, includes the flowmeters and anesthetic vaporizer, and ends at the fresh gas outlet.

High-Pressure Section

Auxiliary E-Cylinder Inlet. During normal operation, the high-pressure section of the anesthesia machine is not active, because the hospital's central gas supply system serves as the primary gas source for the machine. However, it is a requirement to have at least one attachment for an oxygen cylinder to serve as a backup oxygen source in case of failure of the hospital supply. Many machines have up to three and sometimes four E-cylinder attachment points to accommodate oxygen, air, and nitrous oxide. Some machines have attachments for two oxygen tanks, and some rare systems can accommodate carbon dioxide (CO_2) or helium tanks used for special applications. The cylinders are mounted to the anesthesia machine by the hanger yoke assembly, as seen in Fig. 22.3. The hanger yoke assembly orients and safely supports the cylinder, provides a gas-tight seal, and ensures unidirectional flow of gases into the machine.[12,13] Each yoke assembly must have a label designating which gas it is intended to accept. Each hanger yoke is also equipped with the Pin Index Safety System (PISS), which is a safeguard to reduce the risk of a medical gas error caused by interchanging cylinders. Two metal pins on the yoke assembly are arranged to project precisely into corresponding holes on the cylinder head–valve assembly of the tank. Each gas or combination of gases has a specific pin arrangement.[14] Although infrequent, failures of the PISS have been reported, and like all safety systems, the PISS should be considered partial protection. Conditions in which failure occurred have included the following: excessive seating (jamming) of the pins back into the hanger yoke; the presence of bent or broken pins; and an excessive use of washers between the cylinder and the yoke that can override pin alignment, yet allow for a gas-tight seal.[15-17] Medical gas cylinder errors can have tragic outcomes, so it is critical to ensure that the proper gas is being connected to the proper inlet by also checking the tank and yoke labels.[18]

Once a gas cylinder valve is opened by the operator, gas flows first through a filter to entrap any particulate matter from the tank inflow. The maximum pressure in full E-cylinders (approximately 750 psig for nitrous oxide, 2200 psig for air, and 2200 psig for oxygen) is much higher than the normal hospital pipeline supply pressure of 50 to 55 psig. A *high-pressure regulator* reduces the variable high pressure in the E-cylinder to a constant pressure slightly lower than

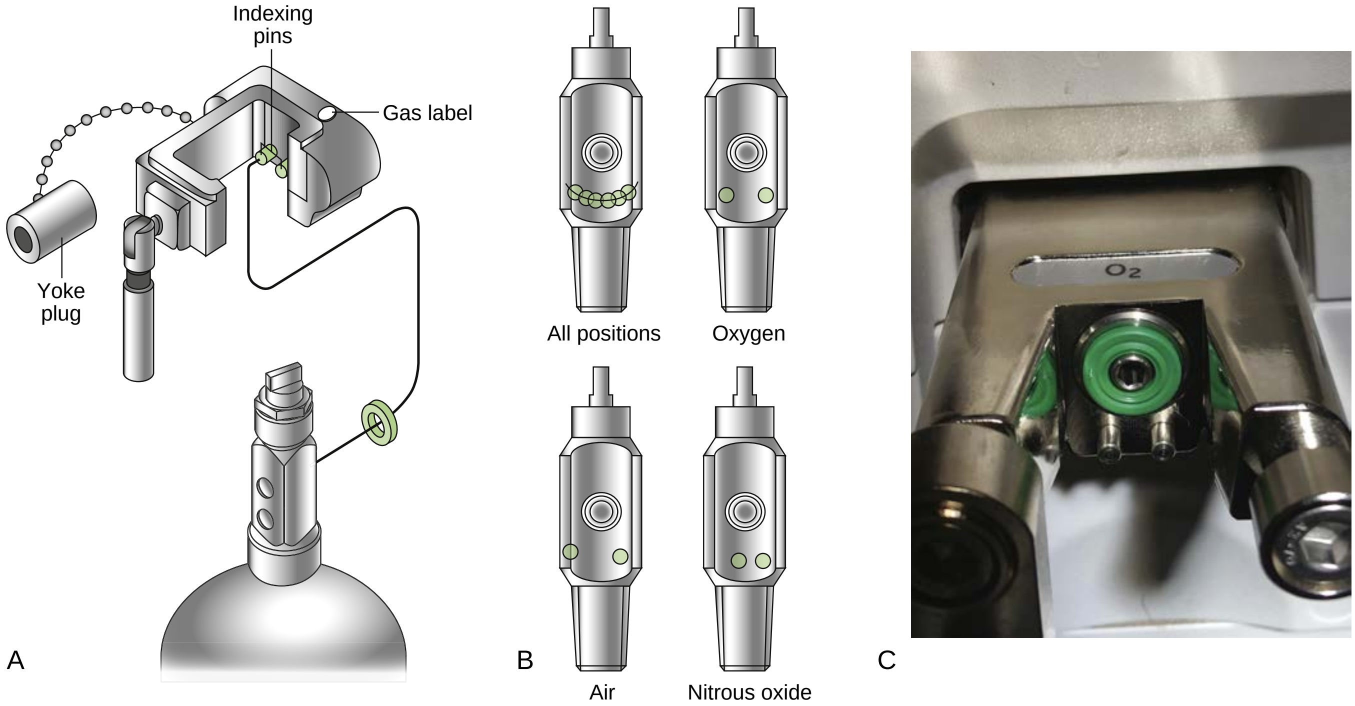

Fig. 22.3 E-cylinder hanger yoke assembly. (A) Standard E-cylinder hanger yoke assembly highlighting the gas-specific indexing pins, sealing gasket, and yoke plug. The yoke plug should be inserted when a tank is not in place. (B) Pin Index Safety System holes machined into the cylinder head–valve mechanism of the compressed gas cylinders. (C) Oxygen yoke with indexing pins. (A and B, From Yoder M. Gas supply systems. In: *Understanding Modern Anesthesia Systems.* Telford, PA: Dräger Medical; 2009.)

the normal pipeline supply pressure, approximately 40 to 45 psig (depending on the specific anesthesia machine)[13] (see the O_2 high-pressure section in Fig. 22.1). The lower pressure is a safety feature: if both the E-cylinder and the oxygen pipeline are connected and the E-cylinder is open, the anesthesia machine will draw its gas from the pipeline rather than the E-cylinder, thereby preserving the contents of the E-cylinder in case of pipeline failure. Fluctuations in the pipeline pressure below 40 to 45 psig could allow the E-cylinder to be drained, as could silent leaks in the high-pressure system, so E-cylinders should be closed during normal operation. One implication of this design warrants emphasis: in case of known or suspected pipeline contamination or crossover leading to delivery of a hypoxic gas mixture (as might be caused by nitrous oxide in the oxygen pipeline), backup oxygen from the E-cylinder will not flow unless the anesthesia machine is disconnected from the pipeline. Merely turning the backup tank on will not help, if the pipeline pressure remains higher than the high-pressure regulator's output.[13,18a]

After the high-pressure regulator, cylinder gas flows through a one-way valve called the cylinder check valve, which prevents any backflow of machine gas out through an empty yoke or back into a nearly empty cylinder (see Fig. 22.1). If the anesthesia machine allows two oxygen E-cylinders to be mounted on a common manifold, then each mount must have a check valve. On some machines, a single high pressure regulator is downstream from the two check valves; on others, each mount on the manifold has its own high pressure regulator and check valve. In either configuration, transfer of gas from a full tank to an empty tank is prevented, and the system allows for a cylinder to be exchanged while the other cylinder on the manifold continues to supply gas to the anesthesia machine.

As noted on Fig. 22.1, there are a number of pressure gauges in the system. The pressure in each of the gas pipelines and each of the auxiliary E-cylinder manifolds must be displayed on the front of the anesthesia machine. The E-cylinder pressures are accurate only when the tank is open; in the case of a two-tank manifold, the pressure of the open tank with higher pressure will be displayed. In systems with electronic pressure displays, the pipeline and tank pressures are visible only when the machine is on.
